Bergen April 2008

SURVEY OF THE FISH RESOURCES OF ANGOLA

**Survey of the demersal resources
10 March – 13 April 2008**

The DR FRIDTJOF NANSEN RESEARCH PROGRAMME is sponsored by the Norwegian Agency for Development Cooperation (NORAD). The Food and Agriculture Organization of the United Nations (FAO) provides support to the Programme through Project GCP/INT/003/NOR: International Cooperation with the Nansen Programme: Fisheries Management and Marine Environment. This project is the follow-up to the Project NORAD/FAO/UNDP GLO/92/013. The Institute of Marine Research (IMR), Bergen, Norway is responsible for the implementation of the Programme in cooperation with FAO Fisheries Department and the local fisheries administrations. The aim of the Nansen Programme is to assist developing countries in fisheries research, management and institutional strengthening.

The programme has previously conducted the following demersal surveys in the area:

January 1985	-	June 1986	(6 surveys)
January 1989	-	December 1989	(3 surveys)
May 1991	-	September 1992	(3 surveys)
January 1994	-	March 2008	(16 surveys)

CRUISE REPORTS "DR. FRIDTJOF NANSEN"

SURVEYS OF THE FISH RESOURCES OF ANGOLA

**Survey of the demersal resources
10 March – 13 April 2008**

CHAPTER 1 INTRODUCTION

1.1 Objectives

The objectives of the cruise had been previously discussed and agreed upon by the responsible of the Demersal Programme of the Instituto Nacional de Investigação das Pescas (INIP), of Angola, and the responsible from the Institute of Marine Research, Bergen (IMR) for the Angolan Demersal Programme, and were the following:

- To survey, map and describe the distribution, composition and abundance of the main demersal species, with special emphasis on seabreams (Sparidae), croakers (Sciaenidae), grunts (Haemulidae), groupers (Serranidae), hakes (Merlucciidae) and shrimps (*Parapenaeus longirostris* and *Aristeus varidens*) on the Angolan shelf and slope (down to 800 m), from Cunene River (17°14'S) to Tombua* (15°40'S), and from Benguela (12°35'S) to Congo River (06°00'S) using bottom trawl and the swept-area method.
- To collect biological data as length, weight, sex and maturity of *Dentex macrophthalmus*, *D. angolensis*, *Pagellus bellottii*, *Pseudotolithus typus*, *Merluccius polli*, *A. varidens*, *P. longirostris*, *Chaceon maritae* and *Panulirus regius*, and to collect the stomach contents and gonads for some species such as *Dentex angolensis*, *Pagellus bellottii*, *Pseudotolithus senegalensis*, *Umbrina canariensis* and *Brachydeuterus auritus*, for future analyses in the INIP Lab.
- To monitor the general hydrographic conditions using a CTD-sonde on each trawl station and map the temperature, salinity and oxygen along standard INIP hydrographic profiles.

From February 2008, INIP has decided to conduct four monitoring hydrographic transects located in Namibe, Lobito, Pta das Palmerinhas and Moita Seca (Congo River). These transects are based on INIP standard profiles but modified and updated according to regional requirements as advised by Dr. Larry Hutching.

*The Tombua-Benguela region has been excluded in all the demersal surveys as the bottom is very steep and rocky and unsuitable for bottom trawling, however, the abundance of demersal species in the region is low as the shelf and the slope are very narrow. The trends in the time series of the demersal biomass estimates are therefore insignificantly affected by the exclusion of the region.

1.2 Participation

The scientific staff consisted of:

From INIP, Silvi Nsiangango (10/3-26/3, Local Cruise Leader), Kumbi Kilongo (26/3-13/4, Local Cruise Leader), Virgílio Estévão (10/3-13/4), Domingos Pedro (10/3-13/4), Pedro Panzo (10/3-26/3), Erikson Saquenia (10/3-13/4, Namibe), Vanaquissa Jonico (10/3-26/3, Benguela), Eusébio dos Santos (10/3-13/4), Paula Faria (10/3-26/3), Filipe Vianda (10/3-13/4), Henriette Lutuba (26/3-13/4), Gisela Ramos (26/3-13/4), David Kisungo (26/3-13/4, Benguela), Fátima Delicado (10/3-26/3),

From IMR, Norway: Åge Høines (10/3-26/3, Cruise Leader), Else Torstensen (26/3-13/4, Cruise leader), Magne Olsen (10/3-26/3), Diana Zaera (26/3-13/4), Jan Frode Wilhelmsen (10/3-13/4), Andreas Nieuwejaar (10/3-13/4)

1.3 Narrative

R/V “Dr Fridtjof Nansen” departed Walvis Bay, Namibia, the afternoon 11 March 2008 and steamed northwards, one day later. This was caused by delayed equipment necessary for the environmental survey on the Angolan shelf starting April 15th. The sampling started in the morning March 13th with trawl and hydrographic stations off Cunene River. A standard geographical allocation of the trawl stations to be taken during the Angolan demersal trawl surveys was implemented in 2003, and the station positions in the southern region have been similar in the 2000 and 2003-2008 surveys. The slope off Baía dos Tigres has not been adequately surveyed as the bottom is very steep and rough between 200 and 600 m. In the evening of March 18th the survey of the southern region was finished. Standard hydrographic transects were sampled west off Baía dos Tigres, Pta. Albina and Cabo de Santa Marta, while off Namibe it was a monitoring line. Zooplankton was sampled with a multinet and phytoplankton with the bottles on the CTD at the Namibe transect. No trawling was carried out in the Tombua–Benguela area as the shelf and slope are very steep and the bottom conditions are therefore not suitable for trawling.

In the evening March 18th the trawling started in the central region. The vessel called Luanda in the afternoon of March 24th to change Norwegian and Angolan scientists. It departed the afternoon of March 27th to continue the survey in the central region. The survey of the central region was completed on March 29th at 18:21 UTC and continued to the northern region. Three standard hydrographic transects (Salinas, Pta. do Morro and Cabo São Braz) and two monitoring lines (Lobito, and Pta. das Palmerinhas, both with plankton sampling) were carried out in the central region. Transects off Lobito and Pta. das Palmerinhas were carried out in accordance with the standards for monitoring lines run by INIP. This was somewhat different than the standard transects run by Dr. Fridtjof Nansen in earlier years, but it was decided by INIP that it was necessary to cover these transects in this manner to maintain their time series on these monitoring lines. The transects ended further off-shore and the distance between the stations were longer than the standard “Nansen” transects run earlier. These “Nansen” transects were selected as the Angolan monitoring lines (Namibe, Lobito, Ponta das Palmerinhas and the Congo River) according to the regional requirements. They were updated and modified as follows: the first station located at 2.5 nautical miles away from the coast, the second at 5 n.miles away from the first station and the third at 10 n.miles away from the second until reaching the isobaths of 2000 m. These principles allow avoiding stations too close from each other which contain almost the same information, therefore reduce the number of stations and allow access to information from deeper areas.

A standard hydrographic transect was carried out at Ambriz and one monitoring line at Ponta da Moita Seca (Congo River) in the northern region. The survey finished in the afternoon of April 11th when R/V “Dr. Fridtjof Nansen” called port in Luanda.

CHAPTER 2 METHODS

2.1 Survey effort

Table 2.1 presents the surveyed area by depth strata, allocation of trawl stations, total number of successful swept-area hauls, number of hauls failed, number of CTD stations, and the distance surveyed. Table 2.1 also shows the allocation of effort relative to the stratum size as percentage hauls versus percentage area, by depth, by region, and by total area. The overall average coverage was 1 valid trawl station per 84 nautical miles (NM²). Figures 2.1-2.3 show the cruise tracks in the southern, central and northern regions, respectively, and the locations of bottom trawl, plankton and hydrographic stations.

Table 2.1 Survey's design and effort for the 2008 demersal survey. Size of the survey area by depth stratum, allocation of trawl stations, proportion of stations relative to stratum size, total number of successful swept-area hauls, number of hauls failed, number of CTD stations, and the distance surveyed, divided in to: southern region (Cunene to Tombua), central region (Benguela to Luanda) and northern region (Luanda to Congo River).

A stratified semi-random survey design was used with depth and area as stratifying variables. Trawling was carried out along transects perpendicular to the coast, which were approximately 15 NM apart (Figures 2.1-2.3), and the allocation of trawl stations was proportional to stratum size. The planned design was sometimes slightly modified due to unsuitable bottom conditions or, in the northern region, due to non-accessible areas with oil exploitation.

Based on a decision made in 2003 the trawl positions of the 2000 demersal survey should be the standard for future surveys in the southern region as the survey had a reasonable good coverage. Furthermore, it was decided that the trawl positions of the 2002 demersal survey should be used as the standard for future surveys in the central and northern regions, as the survey had a good coverage of the regions. Therefore, the station positions and effort have been similar during the 2000, 2003-2008 surveys in the southern region, and during the 2002-2008 surveys in the central and northern regions (see Annex VIII).

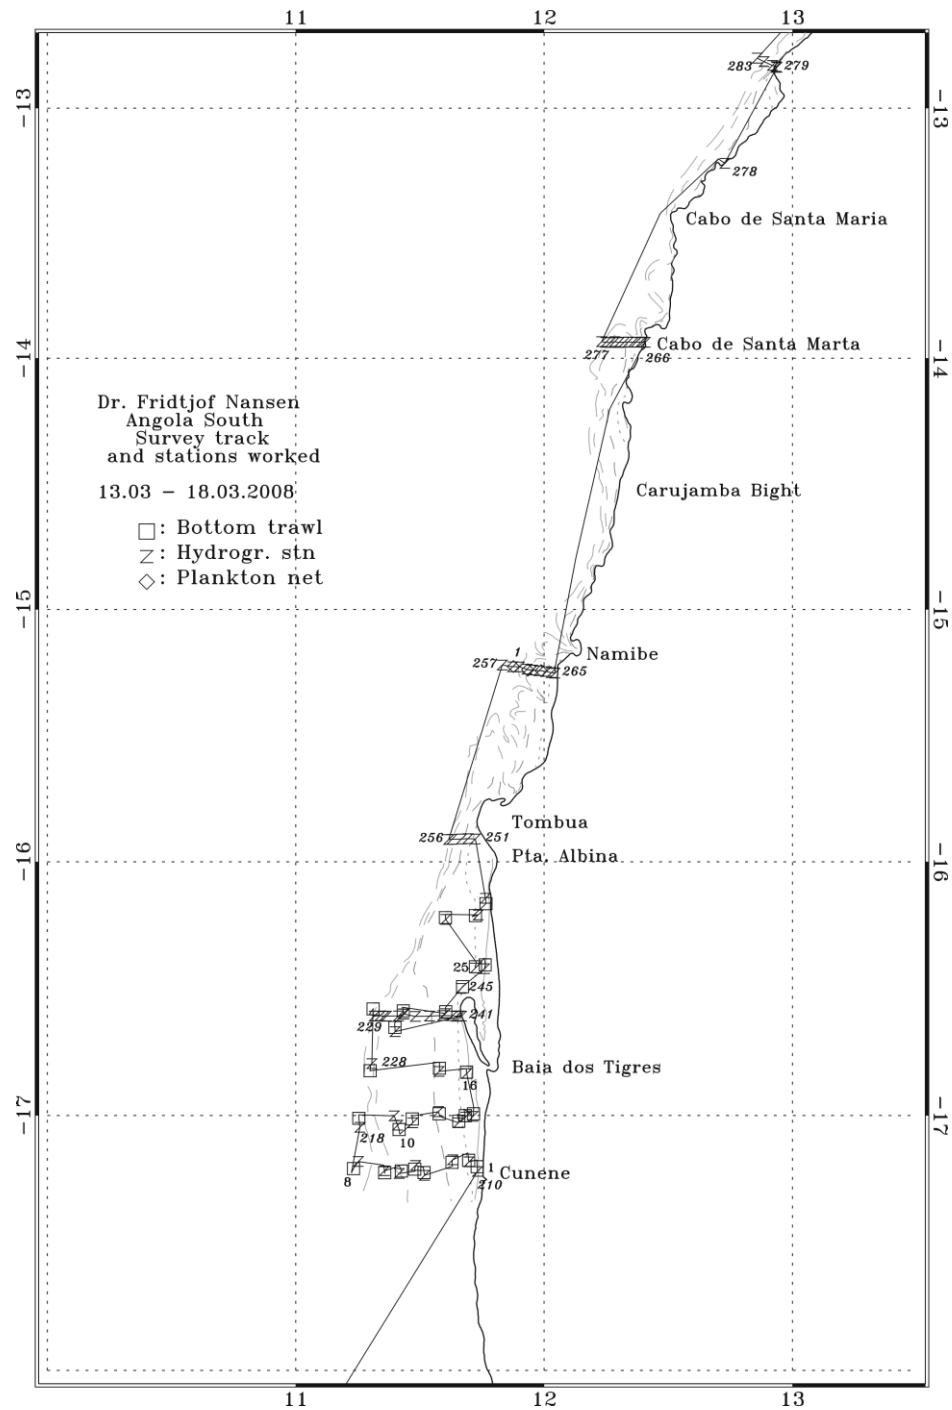

Figure 2.1 Angola south: Cunene - Tombua. Course track with trawl stations, plankton stations and hydrographic transects. Hydrographic stations were also taken at every fishing station. Depth contours at 20, 50, 100 and 200 m.

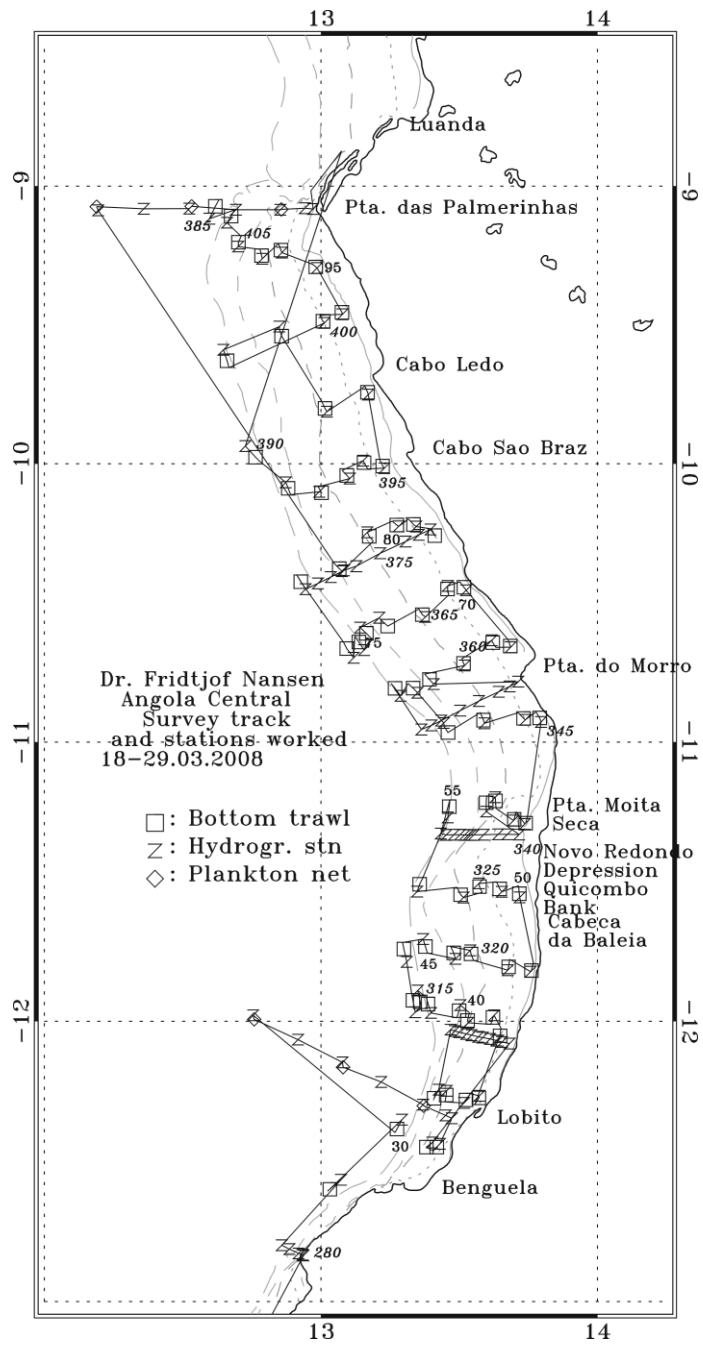

Figure 2.2 Angola central: Benguela - Luanda. Course track with trawl stations, plankton stations and hydrographic transects. Hydrographic stations were also taken at every fishing station. Depth contours at 20, 50, 100, 200 and 500 m.

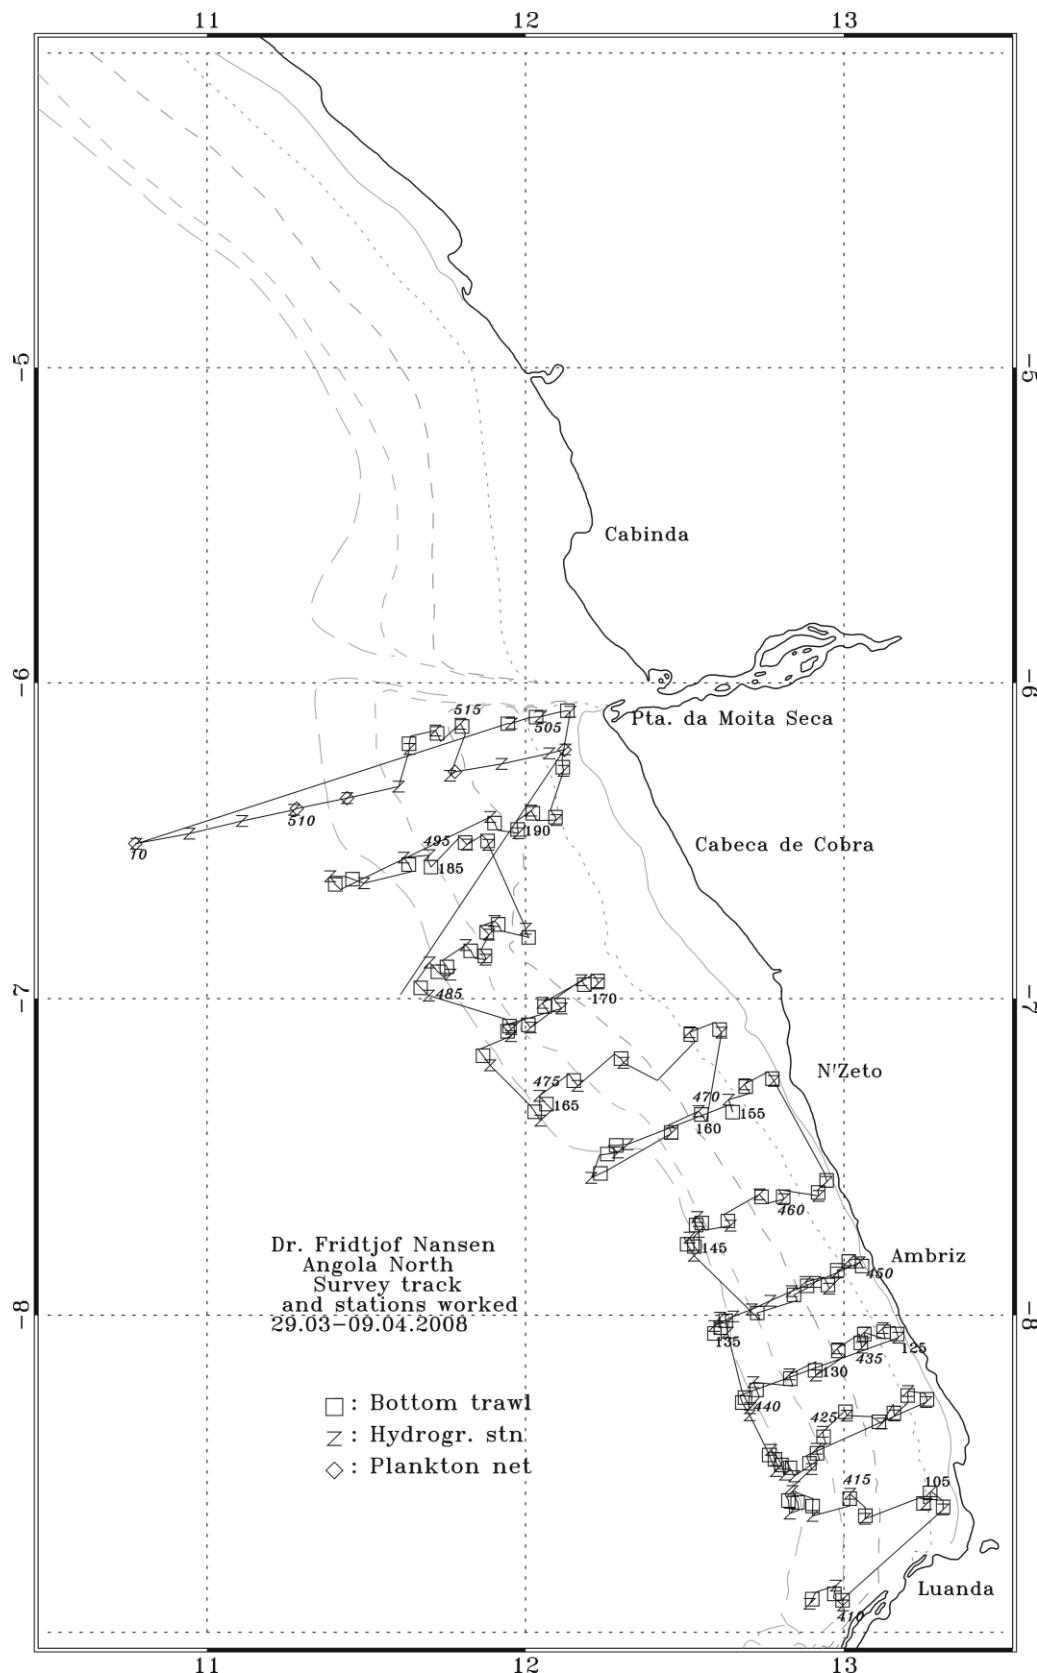

Figure 2.3 Angola north: Luanda - Congo River. Course track with trawl stations, plankton and hydrographic transects. Hydrographic stations were also taken at every fishing station. Depth contours at 20, 50, 100, 200 and 500 m.

2.2 Meteorological and hydrographic sampling

Hydrographic transects modify as recommended by INIP are shown in the table below:

Transects	Classification	Number of stations	
		BEFORE	NOW
CUNENE	STANDARD INIP TRANSECT	8	8
BAIA DOS TIGRES	STANDARD INIP TRANSECT	3	3
PTA ALBINA	STANDARD INIP TRANSECT	5	5
NAMIBE	INIP MONITORING TRANSECT	8	8
CABO DE SANTA MARTA	STANDARD INIP TRANSECT	11	11
LOBITO	INIP MONITORING TRANSECT	11	9
CABEÇA DE BALEIA	STANDARD INIP TRANSECT	5	5
PONTA DO MORRO	STANDARD INIP TRANSECT	9	9
CABO LEDO	STANDARD INIP TRANSECT	4	4
CABO SÃO BRAZ	STANDARD INIP TRANSECT	5	5
PTA DAS PALMEIRINHAS	INIP MONITORING TRANSECT	9	7
AMBRIZ	STANDARD INIP TRANSECT	11	11
NZETO	STANDARD INIP TRANSECT	8	8
CABEÇA DE COBRA	STANDARD INIP TRANSECT	10	10
PTA DA MOITA SECA	INIP MONITORING TRANSECT	13	10

A Seabird 911+ CTD probe was used to obtain vertical profiles of temperature, salinity and oxygen. Real time plotting and logging was done with the customised Seabird Seasave software installed on a PC. Profile data were logged down to a few meters above the bottom at all trawl stations. Calibration of the oxygen sensor was carried out but the data were considered unreliable. It was thus decided to use the calibration data from February 2008 (survey 2008401) The calibration formula used was:

$$cOx_{winkler} = 1.04 \pm 0.01 cOx_{CTD} + 0.031 \pm 0.03, \quad R^2 = 0.99$$

Meteorological observations including wind direction and speed, air temperature, global radiation and sea surface temperature (SST) were automatically logged using an Aanderaa meteorological station and averaged by every nautical mile distance sailed.

A vessel-mounted Acoustic Doppler Current Profiler (VMADCP) from RD Instruments logged the current profiles continuously, and was set to ping synchronously with the echo sounders. The frequency of the VMADCP is 150 kHz, and data were averaged and stored in 3 m or 4 m vertical bins.

2.3 Biological sampling

Sampling gear

A Gisund Super bottom trawl with a headline height of about 4.5 m was used during the survey, and the doors are of the Thyborøn' combi type. New, and heavier Thyborøn doors than last year, were used (see Annex VII). The distance between the front parts of the wings was about 21 m during deployment at a speed of 3 NM h⁻¹. These settings have been the standard on all swept area surveys with R/V "Dr. Fridtjof Nansen". As in previous surveys, except during the 2002 survey, a 44 m long tickler chain was attached to the footrope on depths of more than 300 m in order to catch more of the bottom dwelling deep-water shrimps. During all tows deeper than 80 m, a 9 m long constraining rope was attached between the wires 130 m in front of the trawl doors. This kept a constant distance between the doors of about 50 m during the trawling. In shallow stations with depths of less than 80 m, the door-to-door distance varied more, depending on bottom type and currents. Data from the door and depth/trawl-height sensors were logged for all tows and are stored in files with CMG format, which makes it possible to study the trawl performance in more detail.

Trawl duration was standardized to 30 minutes. The trawling start time is controlled by using SCANMAR sensors to detect the landing of the trawl on the bottom, and the stop-time is defined as the time when the wires start to haul the net. In some cases the towing was interrupted before 30 minutes either due to poor bottom conditions or too high catches of fish indicated by the installed catch sensors. If the stations were not trusted to reflect the density of fish on the bottom they were recorded as invalid in the NAN-SIS database. Table 2.1 shows the numbers of valid and invalid stations. A detailed description of the fishing gear is given in Annex VII.

Sampling the catches

Catches were sampled for species composition by weight and numbers. The total body length of the fish (cm) was measured to the nearest 1 cm below, the carapace length of shrimps and carapace width of crabs to 1 mm below and the mantle length of squids to 1 cm below. The records of fishing stations are presented in Annex I. For commercially important species, pooled length frequency distributions, in which individual samples are raised to total catch, are shown by area in Annex II.

2.4 Acoustic sampling

Acoustic recordings were carried out at four frequencies: 18, 38, 120 and 200 kHz using a SIMRAD ER60 echosounder. Acoustic data were not processed on board, but all data were stored to files using the EchoLog (SonarData). A detailed description of the acoustic settings is given in Annex VII.

2.5 Plankton sampling

Zooplankton

The sampling was conducted by means of HYDROBIOS Multinet with 5 nets. The nets (180 µm) were remotely opened from the bridge of the vessel. The depth intervals covered were 200 - 150 m, 150 -100 m, 100 -75 m, 75 m-50 m and from 50 m to the surface. In the case of stations shallower than 50 m, the sample was taken from the bottom and up to the surface. A SCANMAR depth sensor gave real-time information of the depth and a flowmeter inside the net was used to estimate the sampling volume. The samples were preserved in formalin 4% to be taken to the INIP for further analysis.

Phytoplankton

Phytoplankton samples were taken at each CTD station of the Angola monitoring lines at seven different standard levels. They were defined as follows: 5 m, 25 m, 50 m, 75 m, 100 m, 150 and 200 m depth. The samples were preserved in 4% formalin for further analysis in the INIP.

2.6 Areas and depth strata

Table 2.1 shows the areas, in NM², for the southern region (Cunene-Tombua: S17°14'-S16°00'), the central region (Benguela-Luanda: S12°40'-S09°00'), and the northern region (Luanda-Congo River: S09°00'-S06°00') by depth strata. These strata are used to calculate the swept-area biomass estimates. All valid samples are treated as representative for the relevant depth intervals where the species or group of species were caught.

2.7 Calculations

All equations for the calculations are given in Annex IV. The effective fishing width of trawl gear used by R/V "Dr Fridtjof Nansen" is considered to be 18.5 m. The effective fishing area is the product of the fishing width multiplied by the towing distance measured by the GPS. It

is assumed that all fish within the trawling path are caught, which gives a catchability coefficient (q), *i.e.* the fraction of the fish encountered by the trawl that was actually caught, equal to 1.

The catchability coefficient is seldom known, but because the coefficient is assumed to be constant between surveys the swept-area estimates will reflect any change in population abundances between surveys.

The survey design and effort were previously inconsistent, and made any comparison between surveys difficult. Therefore, it was discussed and agreed upon by the responsible of the Demersal Programme of the Instituto Nacional de Investigação das Pescas of Angola, and the responsible for the Angolan Demersal Programme at the Institute of Marine Research, Norway that all biomass estimates since 1985 should be calculated in a standardized procedure.

Data from the NANSIS database were exported to flat ASCII text files. The software R 2.2.1[⊗] was used to calculate stratified density estimates sorted by survey and stratified by depth and latitude. Biomass estimates by species or species groups were obtained from a stratified mean density estimator using the equations in Annex IV.

CHAPTER 3 OCEANOGRAPHIC CONDITIONS

3.1 Surface distribution

The salient feature of the hydrographic conditions in Angolan waters between December and March is the drop in the salinity at the surface, associated to the seasonal rise in the precipitation over the continent and the consequent increase in the discharge of freshwater carried to the ocean by the Congo River and by other rivers along the Angolan coast. The regular demersal surveys carried out by R/V “Dr. Fridtjof Nansen” in March are coincident with the late phase of the wet season and, typically, it is observed low salinity in the surface waters in the shelf off the northern and central Angola regions. No salinity decrease has been observed off the southern Angola (15–17°S), except of one survey conducted during the anomalous “Benguela Niño” event in February–March 1995.

The horizontal distributions of temperature and salinity in the southern region (March 2008) are depicted in Figures 3.1 – 3.2. The temperature varied between 17–24°C and the salinity was about 35.4–36.0. The temperature off Cunene and Baía dos Tigres was approx. 10 degrees colder in 2008 in comparison with last year; further north the differences were smaller. This gradual and steady increase of temperature from the coast to offshore (17°C–23°C) with a $\Delta T = 4^\circ\text{C}$ was probably due to the seasonal coastal upwelling occurring in this area. The salinity (35.4) also featured the upwelled cold water inshore compared to the surrounding waters with higher salinity (35.9–36). The temperature and salinity distributions indicate the typically features of the presence of the Angola-Benguela Front (ABF).

The horizontal distributions of temperature and salinity in the central region are shown in Figures 3.3 – 3.4. Temperature varies between 25–29°C in the whole region. The salinity values were normal in the whole region and ranged between 34.8 – 35.9, increasing offshore.

In the northern region the temperature was low inshore, around the mouth of the Congo River (about 24.4°C), while the offshore surface water temperature was between 28.5 and 29°C (Figures 3.5 – 3.6). Inshore waters presented very low salinity values, especially around the river’s mouth (29) and increasing at the same latitude to 33 further offshore (Figure 3.6). The river’s plume was observed down to 8.5°S with a salinity of 33.5, while further south there was no sign of freshwater.

Because of high density of oil rigs, supply and seismic vessels, the transect off Pta. De Moita Seca was moved 7 NM south, parallel to the former transect.

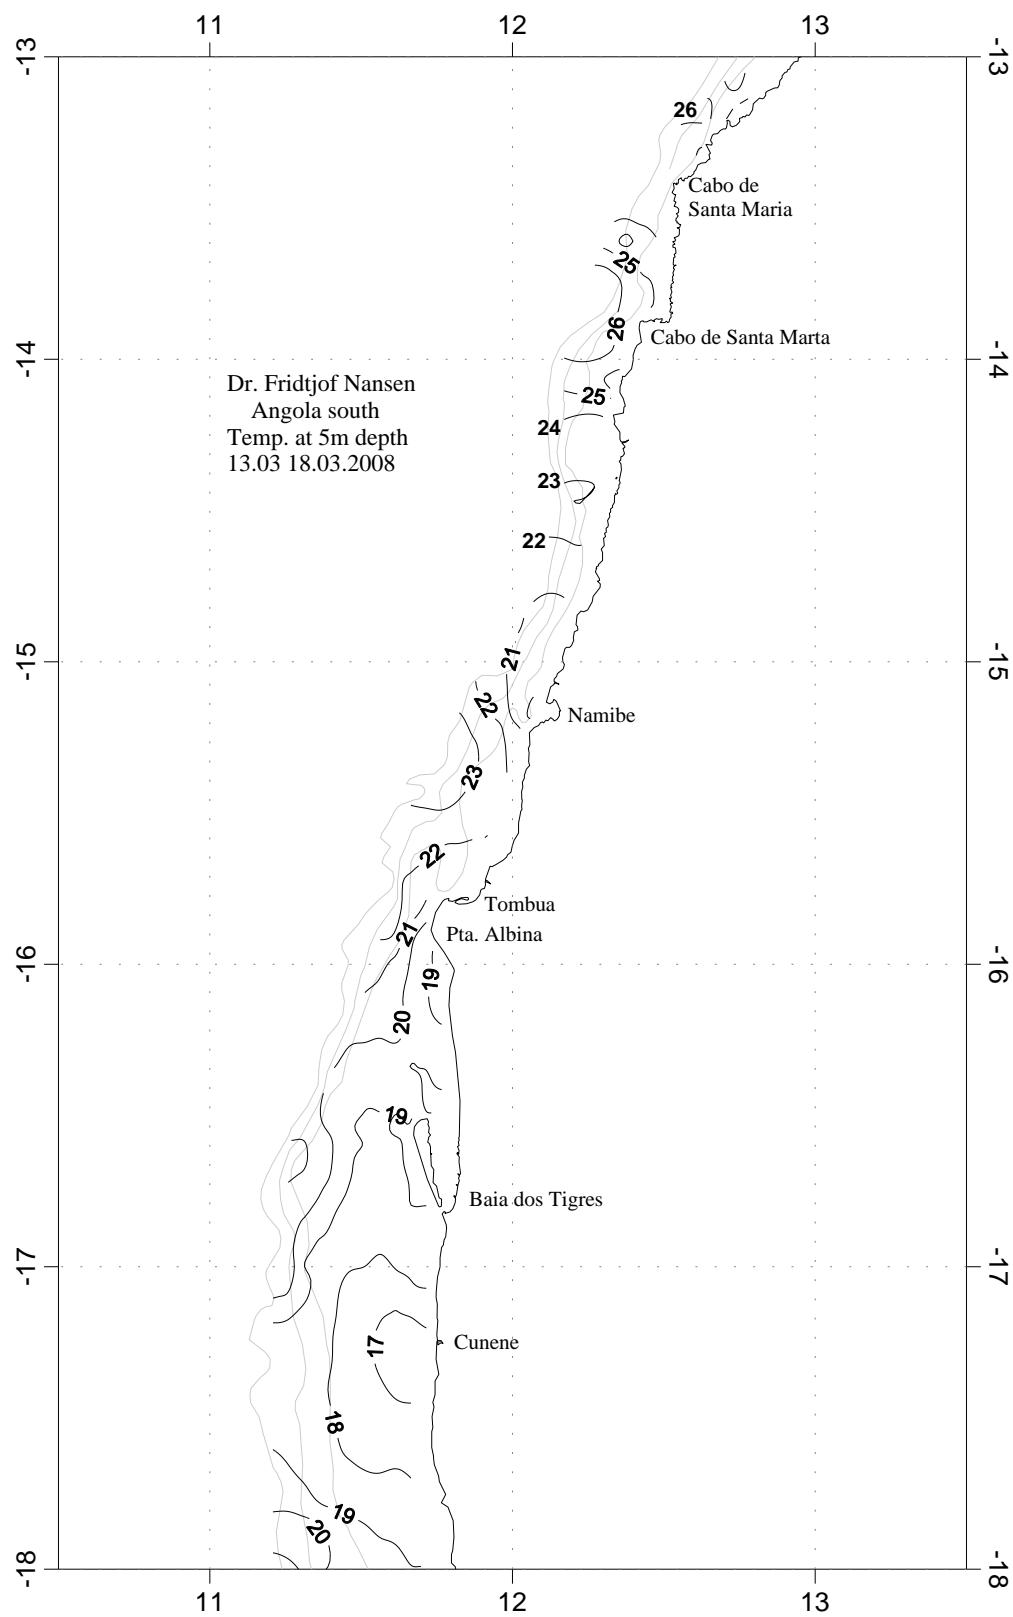

Figure 3.1 Angola south. Horizontal distribution of surface temperatures (5 m depth). Depth contours at 20, 50, 100, 200, 500 and 1000 m.

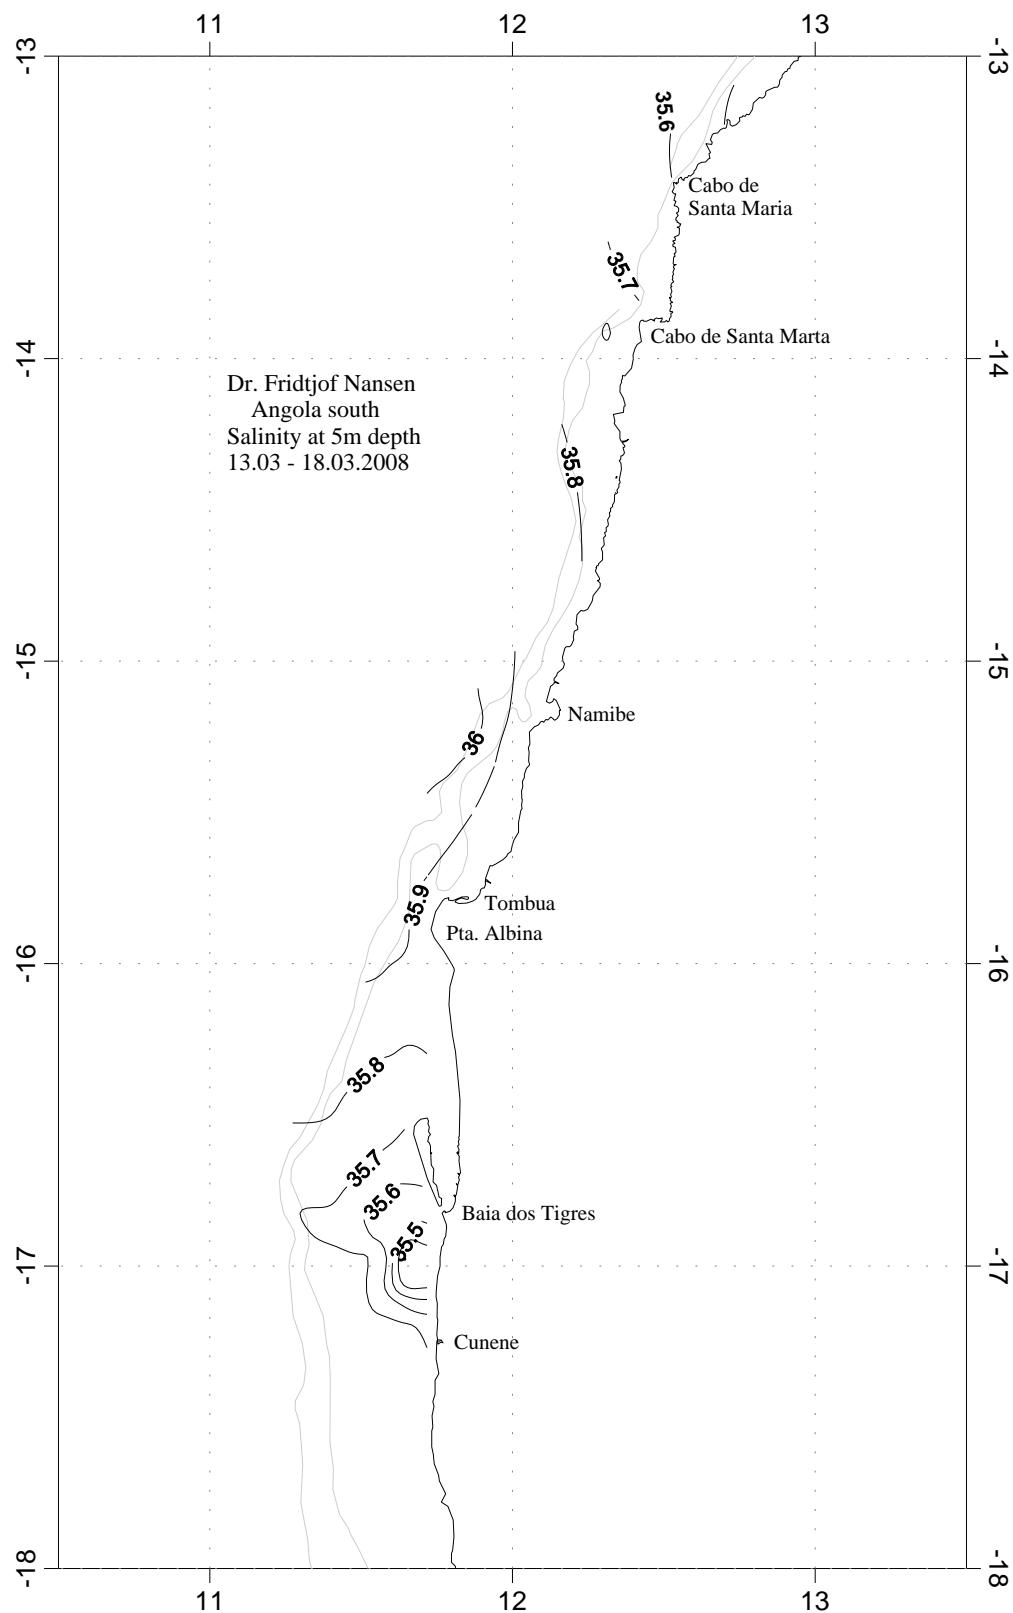

Figure 3.2 Angola south. Horizontal distribution of surface salinity (5 m depth). Depth contours at 20, 50, 100, 200, 500 and 1000 m.

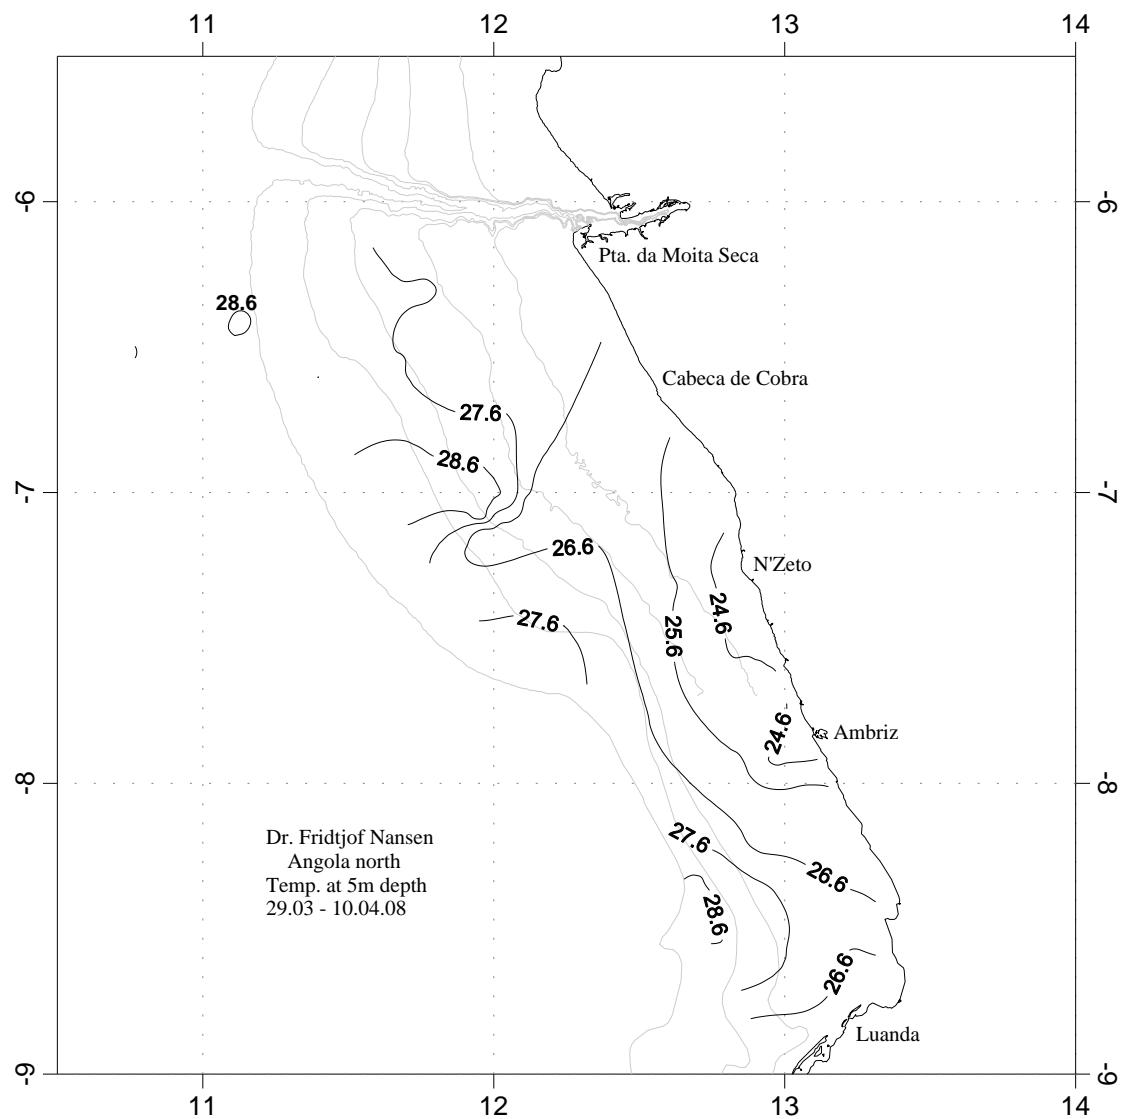

Figure 3.5 Angola north. Horizontal distribution of surface temperature (5 m depth). Depth contours at 20, 50, 100, 200, 500 and 1000 m

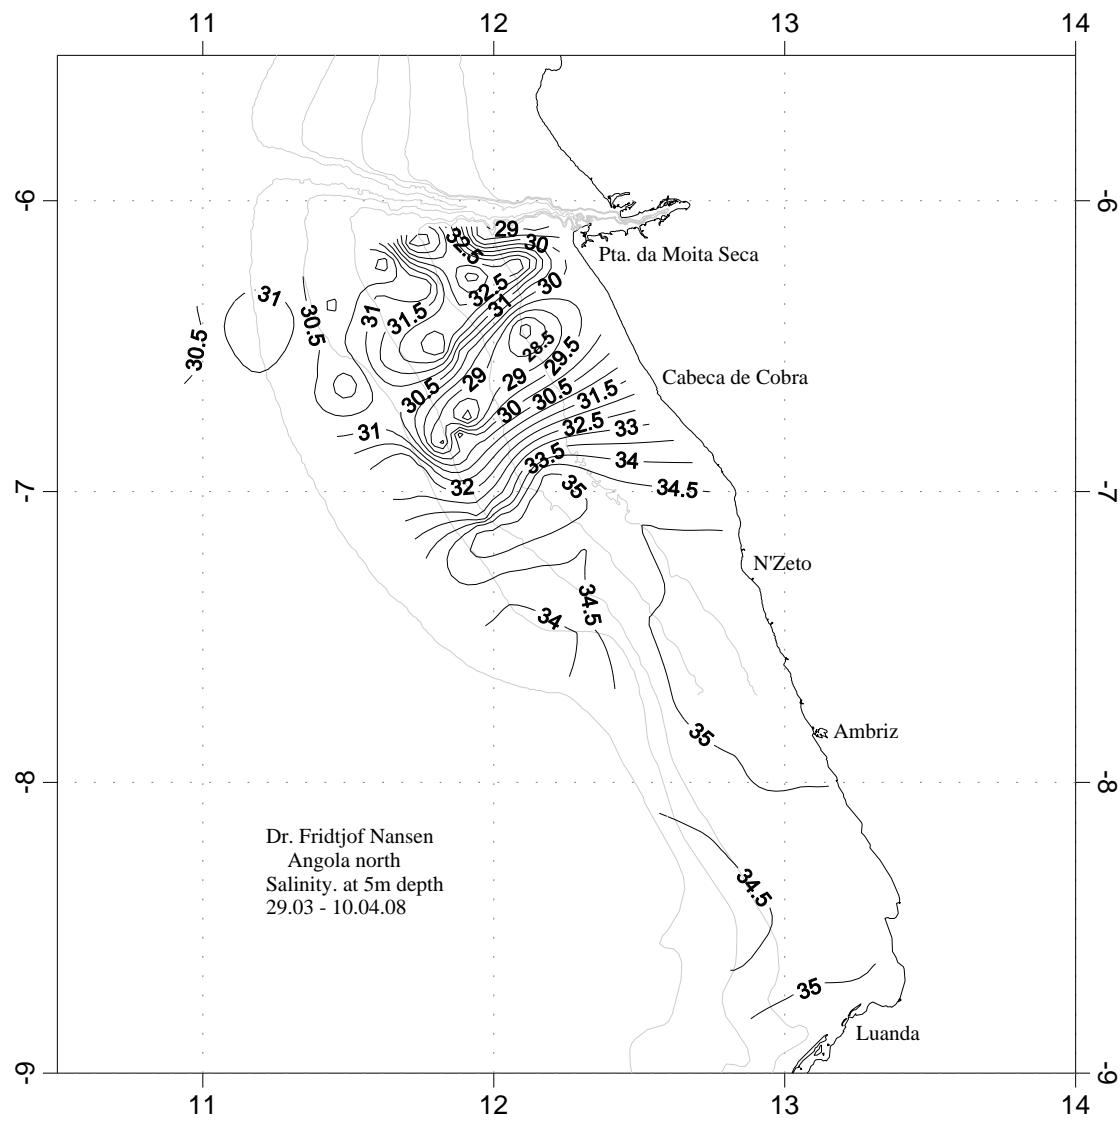

Figure 3.6 Angola north. Horizontal distribution of surface salinity (5 m depth). Depth contours at 20, 50, 100, 200, 500 and 1000 m

3.2 Vertical sections

The vertical transects off Baía dos Tigres, Pta. Albina, Namibe and Cabo de Santa Marta were taken in southern region (Figures 3.7-3.10). By mistake the Namibe transect was taken as a standard instead of as monitoring. In most of the southern transects, it was observed an increase of temperature, salinity and oxygen from the coast to offshore and a decrease with the depth. Off Baía dos Tigres surface temperatures were between 5 and 10°C lower than what was observed last year in the same transect. As reported earlier, this may indicate coastal upwelling.

Especially off Namibe, surface temperatures were lower (23°C) compared to other areas of Angola. It is believed that the origin of cold water off Namibe is due to the intrusion of the Benguela water. Meanwhile cold water observed in Namibe, does not feature high salinity (35.9-36.0). The stratification layer was well pronounced from the surface to below 100 m depth. The temperature in this layer varied between 27°C at the surface to 16°C at the edge of the layer. Salinity was lower at the coast (35.8) than in offshore (36.0) and decreased gradually with depth at the rate of 0.1 per 50m. The oxygen values decreased with depth, the maximum was observed at the surface (4-5 ml/l) and the lower (<1ml/l) bellow 200m depth.

Five transects were carried out in the central region (Salinas, Lobito, Pta. do Morro, São Braz and Pta. das Palmerinhas, Figures 3.11-3.15). Lobito transect was taken as an Angolan monitoring line. Temperature was high offshore (29 °C) and lower at the coast (27 °C). High stratification was observed in the upper layer with the thermocline at around 30 m. Salinity was very high at the surface (36.0) and decreases at the rate of 0.1 every 50 m depth. Off Lobito, Ponta de Morro and Ponta das Palmerinhas, salinity was between 35.8 and 35.9. Oxygen was around 4 ml/l at the surface reaching a minimum at 100m depth.

The surface temperature in Palmerinhas was between 27°C to 29°C, and decreased to below 8°C at depths bellow 400 m. The surface salinity was generally high (about 35.8), the upper layers were well stratified and the halocline was located at 25 m depth.

The vertical sections off Ambriz and Pta. da Moita Seca were taken in the northern region (Figures 3.16-3.17). The temperature profile off Ambriz is highly stratified. Surface temperature was around 26°C. Salinity was lower at the surface (35.0) compared to the lower layers (35.9). This low salinity at the surface shows the extension of the Congo River's plume down to 8°30'S.

The profile off the Congo River (Pta. da Moita Seca, Figure 2.3) is one of the Monitoring Lines modified and updated according to regional requirements. The original thirteen stations were reduced to ten 10, and the transect was extended up to 2000 m depth.

Temperatures were low (25°C) near the coast and increased gradually offshore reaching 27°C. At the river's mouth salinity was 31.0. Salinity values of 33.0 were maintained offshore at the same latitude. Oxygen concentration was normal with 4 ml/l at the surface and the minimum (< 1ml/l) below 250 m depth.

CHAPTER 4 CATCH RATES, DISTRIBUTION, COMPOSITION AND BIOMASS ESTIMATES OF DEMERSAL RESOURCES ON THE SHELF

The inner shelf is defined to be the area between 20 and 70 m bottom depth, and the outer shelf to be from 71 to 200 m depth. Several of the species, which inhabit the shelf, particularly the seabreams (Sparidae), are also found in deeper waters. These are presented in Chapter 5.

The trawl positions are mapped in Figures 2.1-2.3, and the station information and catch by species are presented in Annex I. Pooled length distributions weighted by the catch of the main species by sector region are shown in Annex II. Further, the mean densities (tonnes·n.mi.²) and the frequency of occurrence of the most important species are shown in Annex III. Annex V shows the various NAN-SIS species codes used for species and groups of species, and Annex VI presents the catch rates of these species and species groups.

4.1 Cunene-Tombua shelf

During 3 days 28 trawl stations were sampled on the southern shelf, where 26 were successfully accomplished. The southern region has not been regularly sampled throughout the years, except for the 2000 and 2003-2008 surveys. Other surveys' results in the time series should therefore be interpreted with caution, as the strategy and design of these surveys were not standardized.

Some trawl stations were interrupted (see Annex I) as high catches of horse mackerel affected the trawl performance, and may have prevented an adequate sampling of the catch.

The average catch per hour on the inner shelf was 2 864 kg/hour and 7 328 kg/hour on the outer shelf (Annex VI). The ‘pelagic’ group dominated on the shelf with 34% and 90% of the mean catch rates on the inner and outer shelf, respectively. The mean catch rates of the ‘demersal’ group were respectively 76 and 312 kg/hour on the inner and outer shelf. Shrimps were only caught in low numbers at one station on the outer shelf, and the average mean catch rates of the cephalopods and sharks were 70 and 1 kg/hour on the inner shelf, and 60 and 8 kg/hour on the outer shelf, respectively. The “other” group contributed to 61% of the average mean catch rate on the inner shelf and 5% on the outer shelf. The high proportion of “other” on the inner shelf was caused by one large haul of Jellyfish. Seabreams (except *Boops boops*) was the most abundant demersal group, and was caught in most of the stations on the shelf. The average catch rate of seabreams on the inner shelf was 70 kg/hour and 249 kg/hour on the outer shelf. *Dentex macrophthalmus* was the dominating seabream. The average catch rates of croakers (mainly *Umbrina canariensis*) on the inner and outer shelf were 5 and 9 kg/hour. No grunts were caught on the shelf in the south. As previously mentioned, the ‘pelagic’ group dominated the catches on the inner shelf, and the carangids, mainly horse mackerel (*Trachurus capensis* and *T. trecae*), was by far the most abundant group with an average catch rate of 954 kg/hour. The average catch rate of the carangids on the outer shelf was 6 572 kg/hour.

Biomass estimates

Table 4.1 shows the time series from 1985 to 2008 of swept-area biomass estimates for commercial species in the southern region. The biomass estimates were calculated by stratifying by depth (20-49, 50-99 and 100-199 m). The sampling intensity in the southern

region has been variable throughout the years and only surveys that have covered each of the strata with at least two stations are included in Table 4.1. The high coefficient of variations (CV) shown in Table 4.1 indicates that the trends in the time series should be interpreted with care.

The biomass estimate of horse mackerel in 2008 was 216 000 tonnes, which is the highest estimate since 2004 and the estimate is doubled since last year. However, the swept-area estimates of the pelagic stocks are unreliable as the bottom trawl is only catching fish close to the seabed. In 2005, the *T. trecae* contributed to less than 1% of the horse mackerel biomass estimate on the southern shelf and to 31 and 67%, respectively, in 2003 and 2004. The contribution of *T. trecae* was 93% in 2007 and 78% in 2008 of the horse mackerel biomass. Small fish (<25 cm) dominated the horse mackerel catches and a large proportion of this was juveniles.

The seabream biomass estimate was about 9 150 tonnes and 80% of this was *Dentex macrophthalmus*. This is a marked decrease from last year, and the lowest in the time series.

The biomass estimate of hake (*Merluccius capensis* and *M. polli*) was 1 700 tonnes. No Benguela hake (*M. polli*) was caught in the southern region during the 2005 survey, while it contributed to about 65% of the biomass in 2008. The hake abundance has declined annually since 2003, and the 2008 estimate is the lowest observed since 1989.

The biomass estimate of the cephalopods in 2008 was 3 250 tonnes, which is more than two times the estimate of 1 450 tonnes in 2007. This is the highest estimate since 1989. It is mainly a considerable increase in the biomass of the Sepiidae, which contribute to the increase in the biomass of cephalopods.

During the last years surveys the biomasses of the croakers have varied considerably between surveys. Therefore, no clear trend in the time series can be seen. However, the 2008 estimate of 400 tonnes is a large decrease from last year's estimate of 4 200 tonnes and it is the lowest in the time series. The estimates of *Umbrina canariensis*, which is one of the most important croakers, also show large annual variation and there is no evident trend in the time series.

The biomass estimate of sharks (includes Chimaeriformes) in 2008 was about 300 tonnes which is a considerable reduction from last years estimate and there has been a decreasing trend since 2006. The 2008 estimate is one of the lowest in the time series.

The biomass estimates of the pelagic species groups are unreliable, as the bottom trawl is not a very suitable sample tool for these groups. However, the 2008 biomass estimates of clupeids and scombrids are considerably smaller than the very high estimate of 2006, and the large fluctuations in the time series do not reflect the true change of abundance of these stocks. Similar, the fluctuations in the hairtails biomass estimates over time are unlikely to represent a reliable reflection of changes in the stock. The biomass trend of the carangids is reflected in the horse mackerel time series as no other carangid species was caught in the southern region in 2008.

Table 4.1 Biomass estimates (tonnes) of important species on the shelf (20-200m) in the southern region. CV values are indicated in brackets.

Distribution

Figure 4.1 shows the distribution of seabreams in the southern survey area. The seabream distribution covered most of survey area shallower than 300 m, and the highest concentrations were scattered throughout the whole distribution area between Cunene River and Baía dos Tigres.

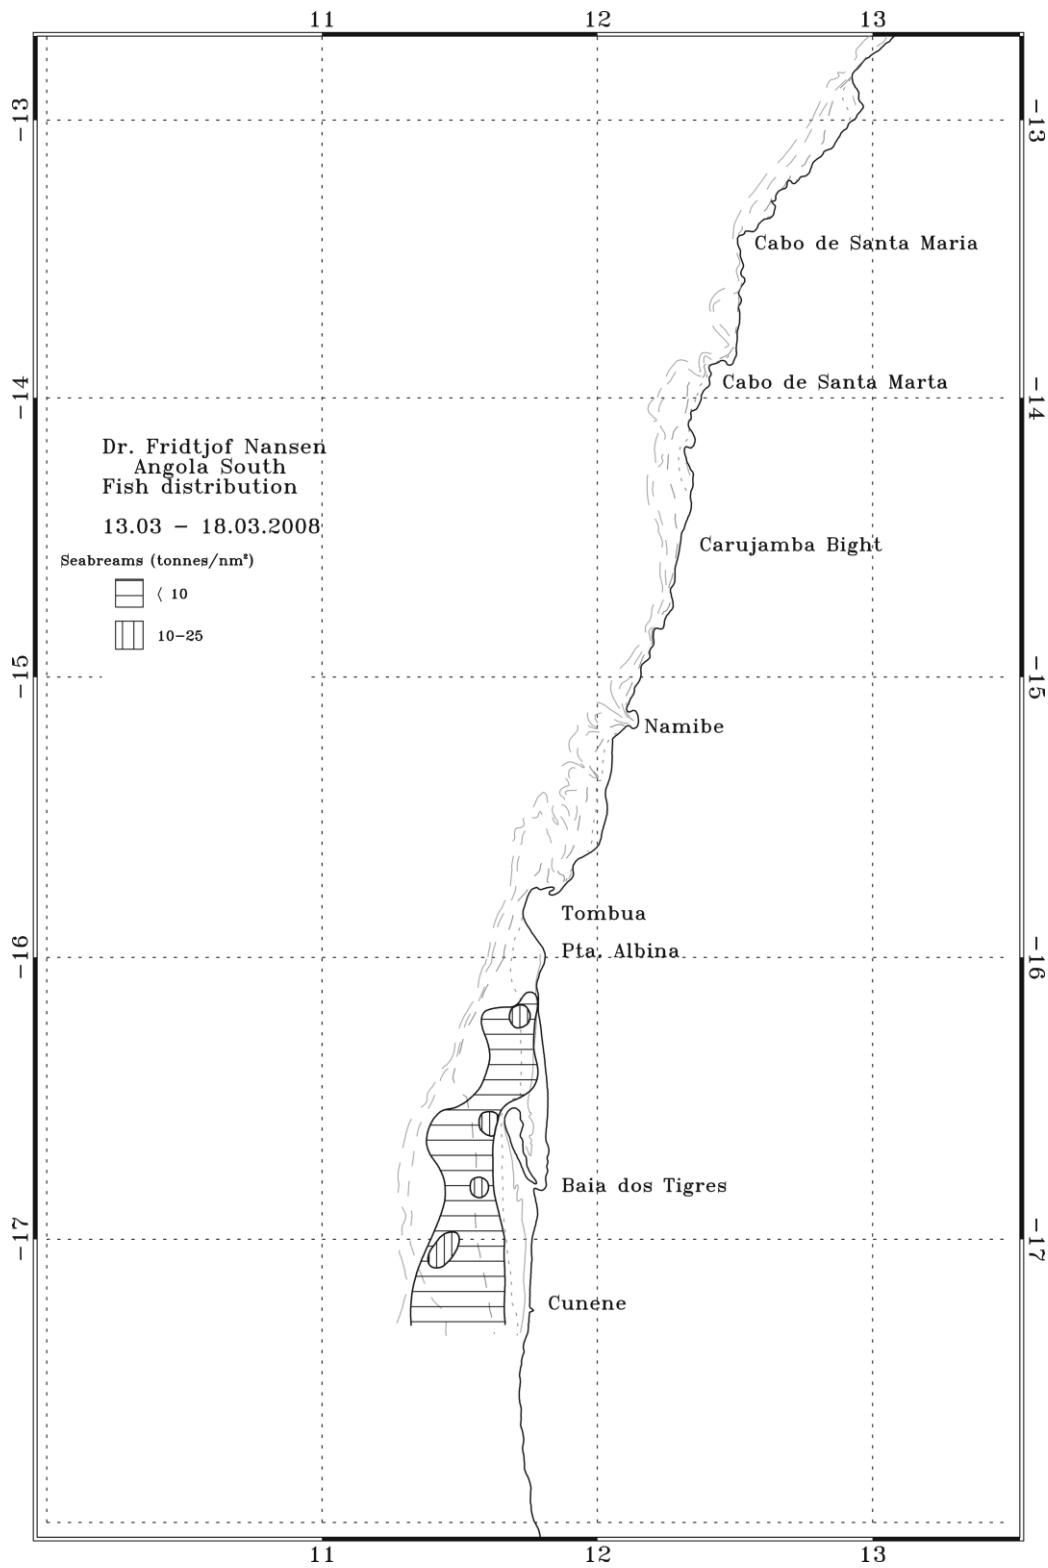

Figure 4.1 Distribution of seabreams (family Sparidae) in the southern region, Cunene-Tombua. Depth contours at 20, 50, 100 and 200 m.

4.2 Benguela - Luanda shelf

The central region of Angolan waters is from Benguela to Luanda. A total of 72 successful swept-area trawl stations were accomplished on the central shelf area (Table 2.1).

The average catch per hour on the inner shelf was 607kg/hour and 415 kg/hour on the outer shelf (Annex VI). The ‘demersal’ group contributed to 58% of the mean catch rate on the inner shelf and the ‘pelagic’ group to 25%. Shrimps contributed to less than 1% in the inner shelf, and the cephalopods and the sharks contributed each to 1 % and less of the total average catch rate. Demersal fish were also more abundant than pelagic fish on the outer shelf contributing to 52% of the average catch rate, whilst the ‘pelagic’ group contributed to 14%. Shrimps contributed to 1% in the outer shelf, and sharks and cephalopods contributed to less than 1% and 3%, respectively. Seabreams (except *Boops boops*) were caught in most of the trawl stations on the shelf, and the average catch rates were 29 and 52 kg/hour on the inner and outer shelf, respectively. The most common seabream species were *D. macrourus*, *D. angolensis*, *Pagellus bellottii*, *D. canariensis* and *D. barnardi*. Snappers were only caught in one station on the inner shelf, but groupers were frequently caught on the inner shelf with an average catch rate of 3 kg/hour. It was not caught on the outer shelf. Similar, the grunts (*Pomadasys incisus* and *P. rogeri*) were often caught on the inner shelf but only found in the shallow part of the outer shelf. The average catch rate of grunts on the inner shelf was 82 kg/hour. Croakers, mainly *Umbrina canariensis*, were frequently caught on both the inner and outer shelf, and the average catch rates were 41 and 23 kg/hour, respectively. The most common pelagic groups on the inner shelf were clupeids, carangids, hairtails and barracudas and the average catch rates of these groups were 16, 58, 52 and 20 kg/hour, respectively. The average catch rates of the same species groups on the outer shelf were 0.3, 28, 28 and 0.1 kg/hour, respectively.

Biomass estimates

Table 4.2 shows the time series from 1985 to 2008 of swept-area biomass estimates for commercial species and groups of species on the shelf off central Angola. The biomass estimates were calculated by stratifying by depth (20-49, 50-99 and 100-199m). The different strata have been sampled with different intensity throughout the time series and Annex VIII shows the numbers of conducted trawls by strata and survey. It must be noted that the biomass estimates presented for the pelagic species may not reflect the true biomass trends, as pelagic species are often unavailable for the bottom trawl. Therefore, the biomass estimates of the pelagic species may more reflect their availability to the trawl than the abundance. Some of the biomass estimates in Table 4.2 have a high coefficient of variations (CV), which indicates that the trends in the time series should be interpreted with care.

T. trecae was the only horse mackerel species found in the central and northern regions, and the biomass on the central shelf decreased dramatically from 2002 to 2005. Although the small improvement from 2005 to 2006 of 7 137 and 9 622 tonnes respectively, the 2008 estimate of 3 703 tonnes is 50% lower than the estimate of 7 600 tonnes registered in 2007. The 2008 estimate is the lowest of the time series since 1985.

North of Benguela, *M. polli* was the only hake species caught, and the 2008 estimate of 22 tonnes was 60% lower than the 2007 estimate of 55 tonnes. The large decrease from the high 2003 estimate of about 1 800 tonnes still needs further investigation.

Seabreams is the most important commercially demersal fish group in Angola. The survey biomass estimates for the central shelf have fluctuated largely throughout the years. In 1991-2002 the total biomass was between 20 000 and 30 000 tonnes, with a peak of 63 200 tonnes

in 1998. The seabream biomass has declined since 1998 and was estimated to 5 800 tonnes in 2008. This is among the lowest estimates in the time series. All the recent estimates are lower than the 2002 estimate of 22 200 tonnes. In the survey from 1991-2 to 2002, the estimated biomass of *Dentex macrophthalmus* made 30-77 % (mean 58%) of the total seabreams estimate, but has contributed to less than 40% (mean 21%) in the 2003-2008 estimates. The biomass of *D. angolensis* has been relatively stable and fluctuated between 1 000 and 2 000 tonnes in recent years. Nevertheless, the biomass of *D. angolensis* decreased from 1 900 tonnes in 2006 to about 1 100 tonnes in 2008. Other important seabreams, which contributed to the total seabreams biomass, were *Pagellus bellottii*, *D. canariensis* and *D. barnardi*.

The biomass estimate of croakers increased from 4 850 tonnes in 2006 to about 8 000 tonnes in 2007 which is the highest estimate since 1999, but decreased to 3 600 tonnes in 2008. *Umbrina canariensis* is the most abundant croaker, and contributed to about 49% of the total croakers biomass.

The 2008 biomass estimate of grunts (*Pomadasys incisus*, *P. jubelini* and *P. peroteti*) was 5 900 tonnes. This value was lower than what was estimated in 2007 (9 200 tonnes), the highest in the time series. However, the estimates have varied considerably between surveys and no clear trend can be seen in the time series.

The snappers are rare in the catches as they inhabit rocky and often untrawlable (bottom trawl) areas. Hence the biomass estimates of snappers do not adequately reflect the state of the stock.

Groupers, mainly *Epinephelus aeneus*, are seldom found on the outer shelf, and as the high CVs indicate the biomass estimates should be considered with care. There is no clear trend in the time series as the survey estimates vary largely between years.

The biomass estimate of *P. longirostris* in 2008 was 230 tonnes, which is a large increase from the 2007 estimate of 36 tonnes. *P. longirostris* is mainly distributed in the deeper parts of the shelf and the slope.

The biomass estimate of Sepiidae was 38 tonnes in 2008, which is a large decrease from the 2007 estimate of 245 tonnes, however, the annually variability and the high CVs may indicate that the estimates do not accurately reflect the state of the stock.

The biomass estimate of Ommastrephidae was 330 tonnes in 2008, which is a large increase from the 2007 estimate of 43 tonnes, the lowest estimate in the time series since 1996.

Table 4.2 Biomass estimates (tonnes) of important species on the shelf (20-200 m) in the central region. CV values are indicated in brackets.

Survey	M.polli	T.treace	Shrimps	Cephalopod	Sharks	Clupeids	Carangids	Scombrids

Distribution

Figure 4.2 shows the distribution of seabreams in the central region between Benguela and Luanda. The distribution was spread out over the whole central shelf with some higher concentrations off Benguela and Lobito.

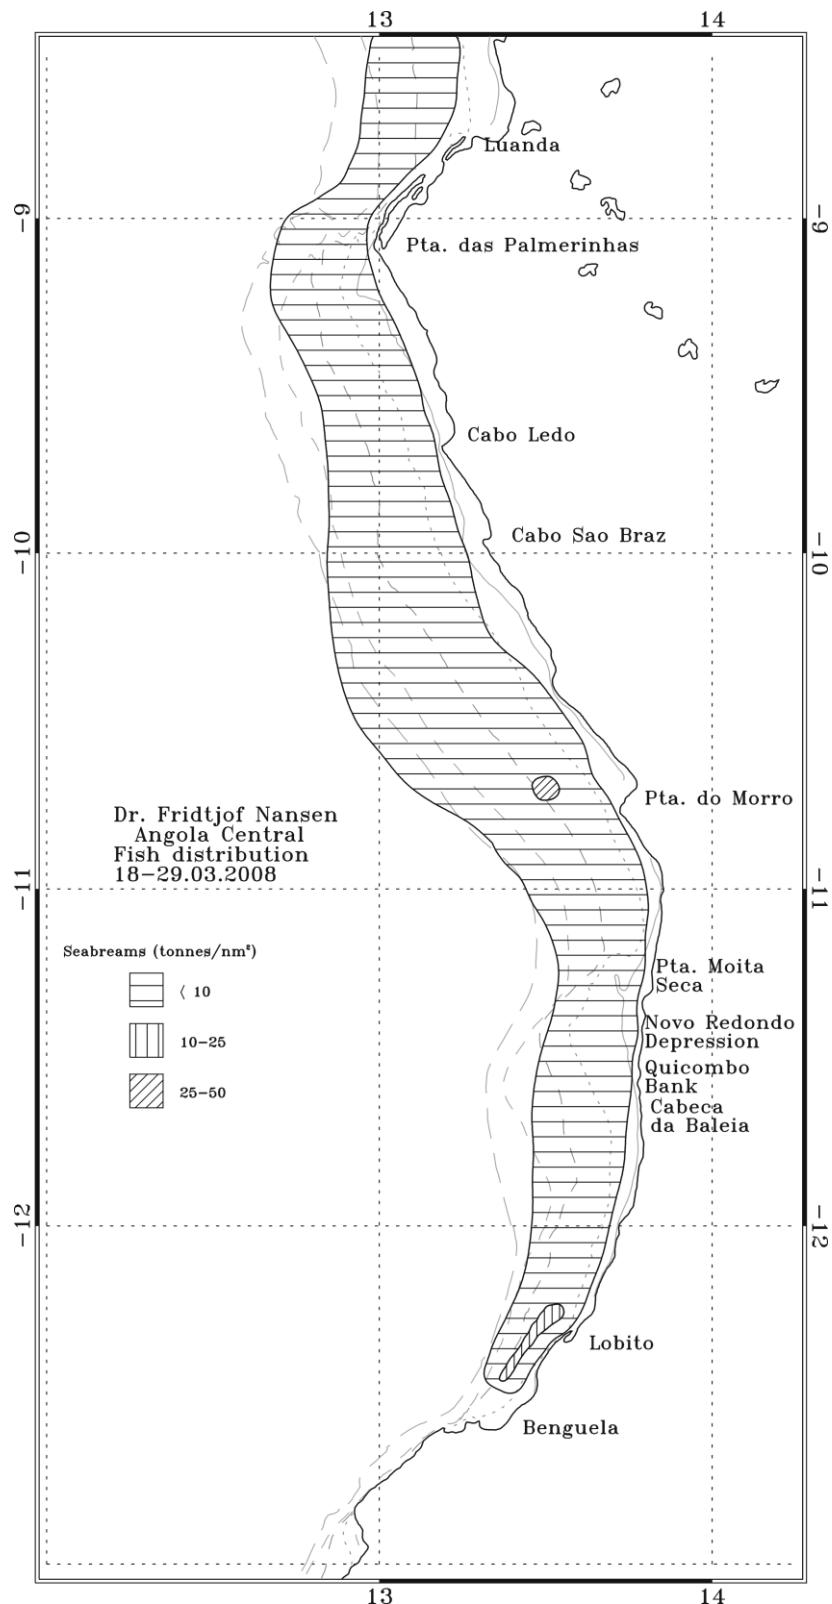

Figure 4.2 Distribution of seabreams (Sparidae) in the central region, Benguela – Luanda. Depth contours at 20, 50, 100, 200 and 500 m.

4.3 Luanda – Congo River shelf

The survey covered the northern region of Angolan waters from Luanda to Congo River. The area north of Congo River is inaccessible to fisheries surveys due to the restricted oil exploitation areas. During some of the previous surveys the area north of Congo River was covered, but to make plausible comparisons the biomass estimates in Table 4.3 only include trawl stations south of Congo River. A total of 59 successful swept-area trawl stations were accomplished on the shelf area in 2008 (Table 2.1).

The average catch per hour on the inner shelf was 1440 kg/hour and 340 kg/hour on the outer shelf (Annex VI). The ‘demersal’ group dominated on the inner shelf with an average catch rate of 920 kg/hour and a relative contribution of 64%. The ‘pelagic’ group contributed about 24%, shrimps and sharks to 0.3% each, while cephalopods to 0.5%. On the outer shelf, the demersal fish contributed to 47% of the mean catch rate and the ‘pelagic’ group to about 28%. Shrimps and sharks each contributed to less than 1% and the cephalopods to 2% of the mean catch rate. Seabreams (except *B. boops*) were caught in all trawl stations at the outer shelf and in about 79% of the stations at the inner shelf, and the average catch rates were 41 and 92 kg/hour on the inner and outer shelf, respectively. Snappers were only caught in one stations on the inner shelf and was not caught in the outer shelf. The catch rates of groupers were 6.4 and 1.6 kg/hour on the inner and outer shelf, respectively. The grunts (*Pomadys incisus* and *P. rogeri*) were caught more often on the inner shelf than on the outer shelf. The average catch rate of grunts on the inner shelf was 17 kg/hour, and 3.4 kg/hour on the outer shelf. Croakers, mainly *U. canariensis*, were frequently caught on both the inner and outer shelf, and the average catch rates were 90 and 30 kg/hour, respectively. The most common pelagic groups on the inner shelf were clupeids, carangids, scombrids, hairtails and barracudas and the average catch rates of these groups were 29, 232, 1.7, 40 and 6 kg/hour, respectively. The average catch rates of the same species groups on the outer shelf were 0.0, 18, 0.4, 74 and 0.3 kg/hour, respectively.

Biomass estimates

Table 4.3 shows swept-area biomass estimates from 1985 to 2008 for the commercial species and groups of species on the shelf off northern Angola. The biomass estimates were calculated by stratifying by depth (20-49m, 50-99m and 100-199m). The different strata have been sampled with different intensity throughout the time series and Annex VIII shows the numbers of trawls that have been carried out by strata and survey. Again, it must be noted that the biomass estimates presented for the pelagic species cannot be trusted as a good reflection of the true biomass as the species are often unavailable to the bottom trawl. Some of the biomass estimates in Table 4.3 have a high coefficient of variations (CV), which indicates that the trends in the time series should be interpreted with care.

The biomass of *T. trecae* was estimated to 1 938 tonnes in 2008, which is the lowest estimate of the biomass registered in the time series since 1996. In this interval of time, the highest estimates of 37 094 tonnes was registered in 1997.

In contrast with the 37 tonnes registered in 2007, *M. polli* was not caught on the northern shelf in 2008.

The 2008 biomass estimate of seabreams on the northern shelf was on the same level as in 2007, 12 800 tonnes, but is still considerably lower than the very high 2005 estimate of 18 300 tonnes which was the highest estimate since 1996. As in the previous years, *Dentex angolensis* is the dominating seabream species in the north and contributes to about 37% of

the total seabream estimate. The biomass of *Dentex macrophthalmus* is low in the northern region and contributes marginal to the total seabream estimate and in 2008 no *D. macrophthalmus* was caught in this region. Other important seabreams are *Pagellus bellottii*, *D. canariensis* and *D. barnardi*. The biomass estimate of croakers, mainly *Umbrina canariensis*, *Atractoscion aequidens* and *Pseudotolithus typus*, was 8 771 tonnes in 2008, which is considerably higher than last year and the highest biomass estimate since 1997. Generally, *Umbrina canariensis* dominates the croakers and in 2008 this species contributes to 36% of the total estimate of croakers.

The biomass estimate of grunts (*Pomadasys incisus*, *P. jubelini* and *P. peroteti*) was 1 485 tonnes in 2008, which is a dramatic decrease from the estimate in 2007 of 7 966 tonnes. However, a fluctuating trend is observed during the 4 last years.

The snappers are rare in the catch as they inhabit rocky and often unavailable areas, hence the biomass estimates of snappers may not adequately reflect the state of the stock.

As in the previous years, groupers, mainly *Epinephelus aeneus*, are seldom found on the outer shelf, and as the high CVs indicate the biomass estimates should be considered with care. Nevertheless, the biomass estimates since 2000 have been relative stable, with a slightly increasing trend the last 3 years.

The biomass estimate of *P. longirostris* in 2008 was 40 tonnes on the northern shelf, which is lower in relation to 2006 and 2007, but still higher than the 2005 estimate of only 5 tonnes. Further investigations are needed to explain the large variation in biomass of *P. longirostris* between surveys.

The 2008 biomass estimate of Sepiidae was 268 tonnes and is considerably higher than the 2006 estimate of 94 tonnes. Although the fluctuating trend of the biomass since 1999, the abundance of Sepiidae is low on the northern shelf.

The biomass estimate of Ommastrephidae increased to 226 tonnes in 2008, from a very low level in 2007, which was the lowest estimate of the time series since 1989. The annual biomass estimates vary and no clear trend in the abundance of Ommastrephidae can be seen in Table 4.3, but it seems like the biomass estimates on the central and northern shelves follow the same trends.

Distribution

Seabreams were distributed on the whole northern shelf (Figure 4.3). The densities were <10 tonnes/NM² along all the area of distribution.

Table 4.3 Biomass estimates (tonnes) of important species on the shelf (20-200 m) in the northern region. CV values are indicated in brackets.

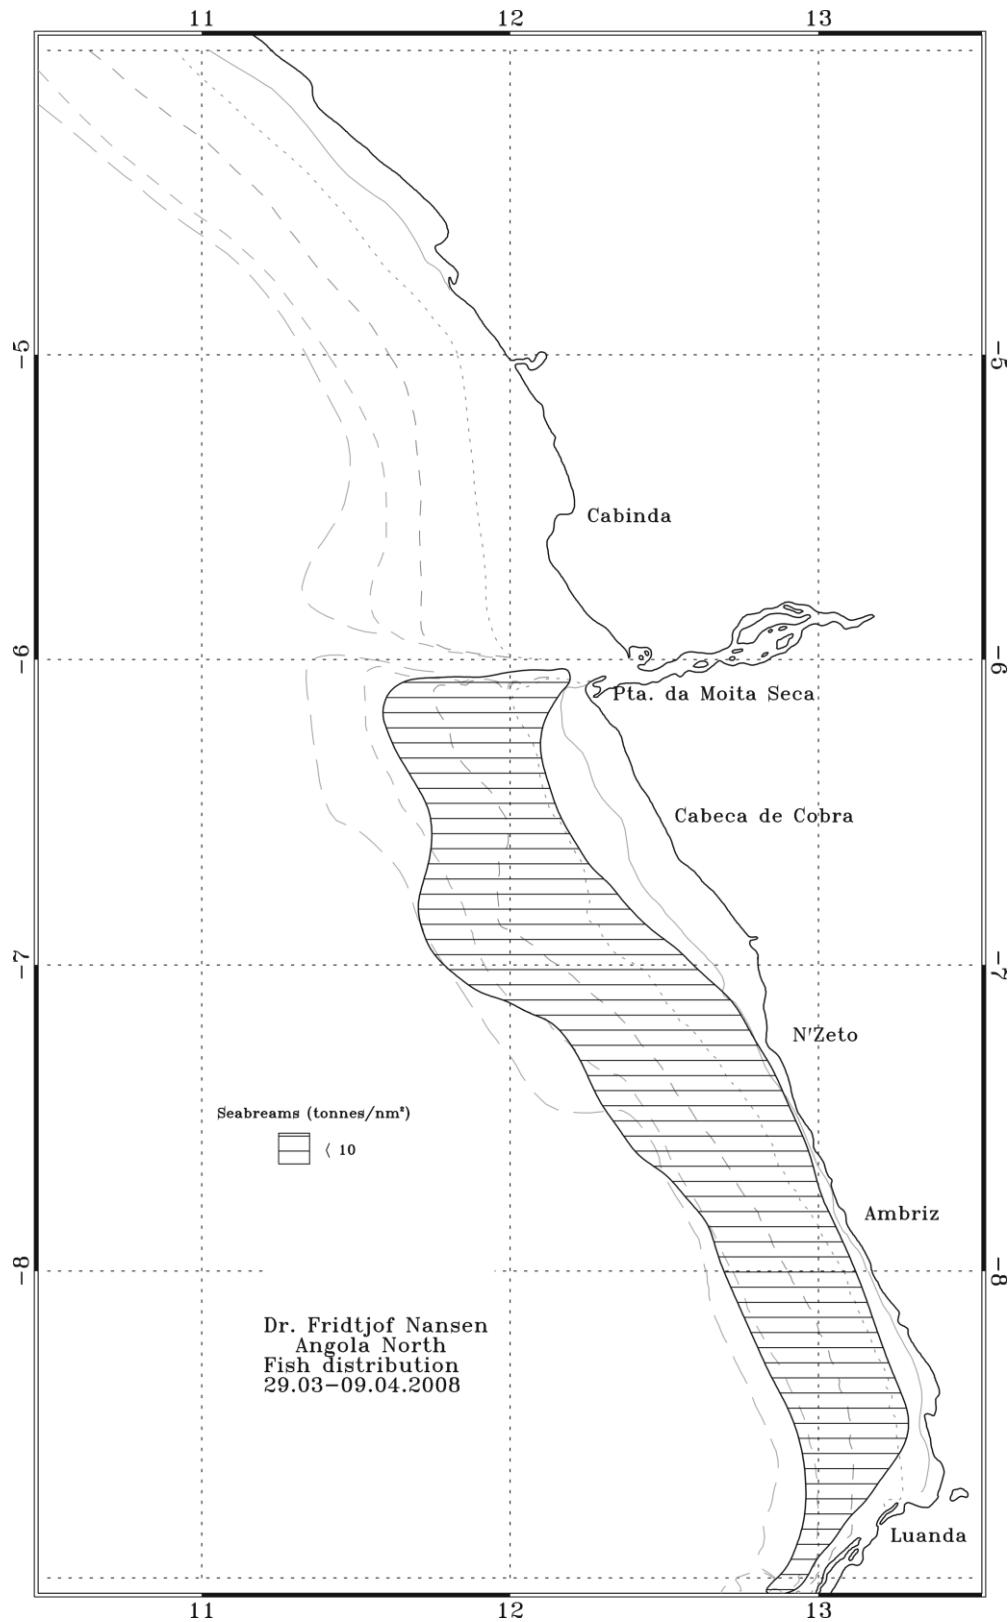

Figure 4.3 Distribution of seabreams (Sparidae) in the northern region, Luanda-Congo River. Depth contours at 20, 50, 100, 200 and 500 m.

CHAPTER 5 CATCH RATES, DISTRIBUTION, COMPOSITION AND BIOMASS ESTIMATES OF DEEP-WATER SHRIMP AND HAKE ON THE SLOPE

The slope is in the report defined to be between 201 and 800 m bottom depth. The trawl positions are mapped in Figures 2.1–2.3, and station information and catch by species are presented in Annex I.

Pooled length distributions weighted by the catch of the main species by sector region are shown in Annex II. Further, the mean densities (tonnes·NM⁻²) and the frequency of occurrence of the most important species are shown in Annex III. Annex V shows the various NAN-SIS species codes used for species and groups of species, and Annex VI presents the catch rates of these species and species groups.

5.1 Cunene – Tombua slope

The slope is very steep and rocky in the south and makes trawling difficult. Five trawl stations were realized on the southern slope in the depths between 200 and 800 meters (Annex VI). The average catch per hour was 2 175 kg/hour, and the ‘demersal’ and ‘pelagic’ groups contributed to 4% and 2%, respectively. The “other” group (non-commercial species) dominated the catches and contributed to 92% of the mean catch rate. Cephalopods, shrimps and sharks contributed to between 1 and 2%. Seabreams were only caught in one trawl haul and this catch contributed to less than 1% of the mean catch of the slope area. Hake (*Merluccius spp.*) was caught at all five stations with an average catch rate of 66 kg/hour. *Aristeus varidens* was found in four of the stations and the mean catch was 14 kg/hour.

Table 5.1 shows the time series from 1986 to 2008 of the swept-area biomass estimates for different species and species groups on the southern slope. The numbers of trawl stations on the southern slope is very low due to the difficult trawling conditions. Therefore, no stratifying by depth is done for the data. Further, only stations in the depth range 200-600m are included in the biomass estimates, and in 2008 as in 2007, just one station was successfully carried out between 200 and 600 meters. The 2008 biomass estimates are therefore not reliable.

The biomass estimates of hake have fluctuated since 2000 (Table 5.1). The 2008 estimate was down from 2007 and with exception of 2005, which was very low, there has been a downward trend in the biomass of hake in the southern area. The lack of any clear trend in the time series is probably caused by the low sampling effort on the southern slope between 200 and 600 meters. The contribution of the two hake species (*M. capensis* and *M. polli*) has varied through the years, and it is reasonable to believe that, in some surveys, a misidentification of the hakes could have happened.

In 2008 there were catches of seabreams, commercially important shrimp species, horse mackerel, and cephalopods on the southern slope (200-600 m), and the biomass estimates were 230, 280, 560 and 9 tonnes, respectively. However, as earlier mentioned these estimates are highly unreliable for the reason that there was only one haul which was the basis for these estimates.

Table 5.1 Biomass estimates (tonnes) of important species group on the slope (200-600 m) in the southern region. CV values are indicated in brackets.

Distribution

Figure 5.1 shows the distribution of hake (*Merluccius spp.*) in the southern region. The distribution covers large parts of the outer shelf and the slope from Cunene to Baía Dos Tigres. The distribution area is somewhat smaller than in 2007.

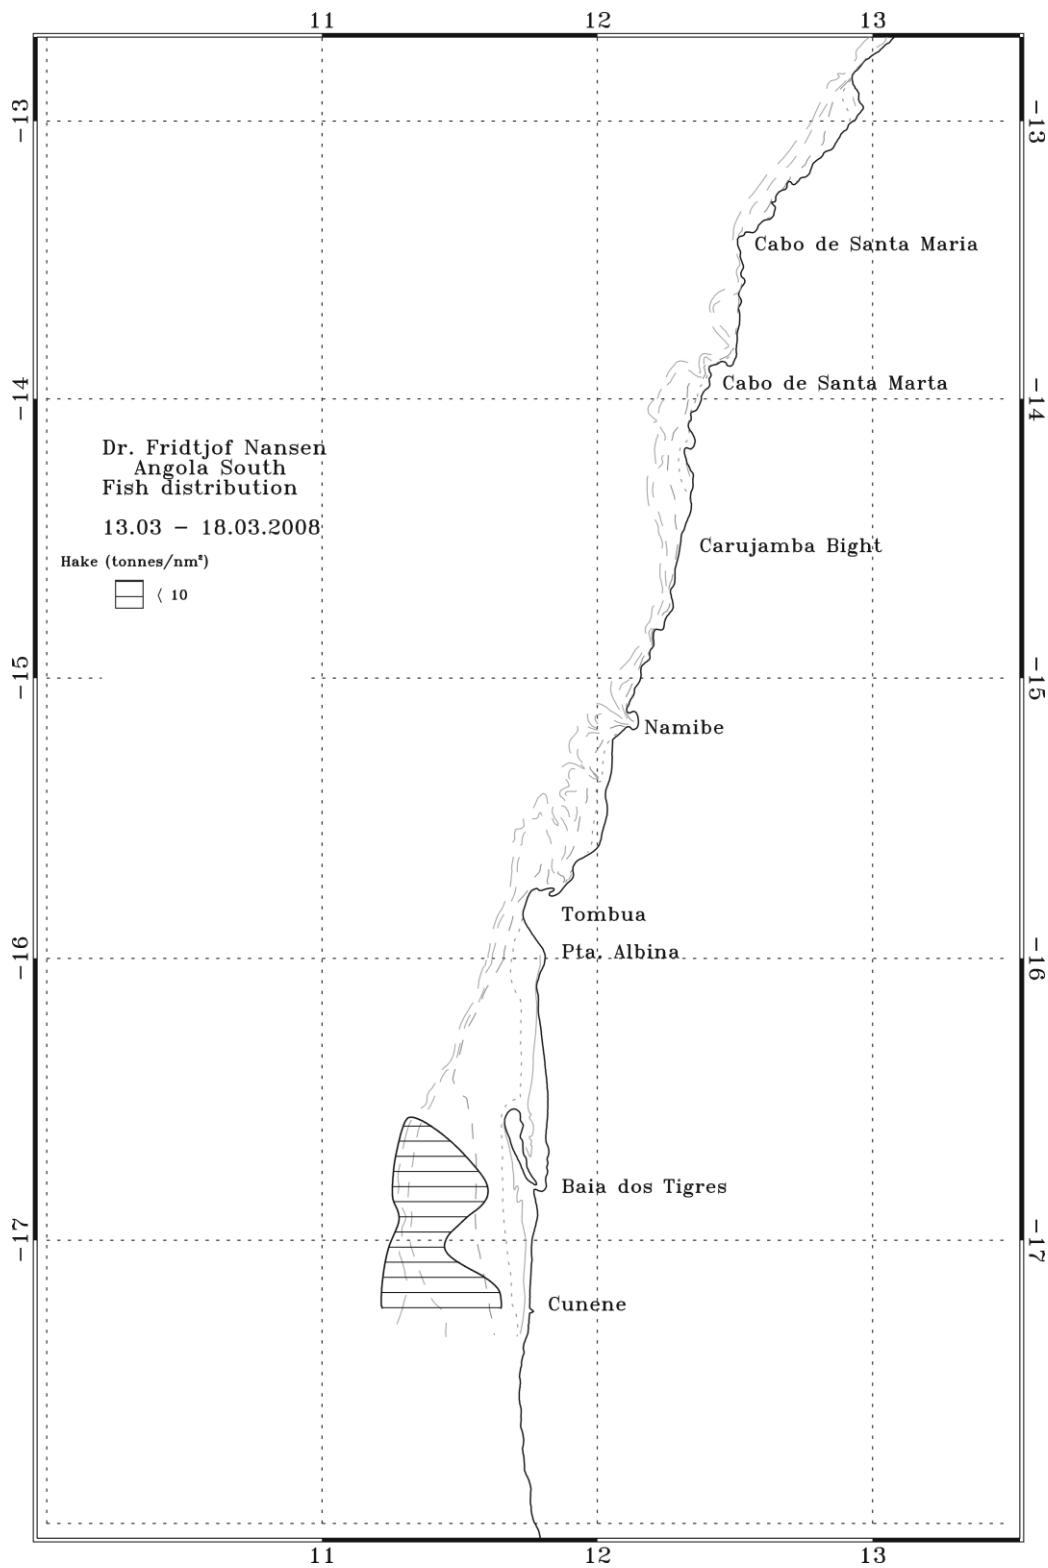

Figure 5.1 Distribution of hake (*Merluccius spp.*) in the southern region, Cunene - Tombua. Depth contours at 20, 50, 100 and 200 m.

5.2 Benguela – Luanda slope

The central region of Angolan waters is from Benguela to Luanda, and a total of 23 successful swept-area trawl stations were accomplished on the central slope (Table 2.1).

The average catch rate on the slope was 463 kg/hour (Annex VI). The ‘demersal’ group contributed to 25% of the mean catch rate and the ‘pelagic’ group to 2%, the shrimps contributed to 20%, while cephalopods and sharks contributed to 1 and 2%, respectively. The “other” group dominated the catches and contributed to 51% of the total mean catch rate. *M. polli* was caught in almost every station on the central slope and the average catch rate was 92.1 kg/hour. The average catch rate of seabreams was 13.2 kg/hour, but the group was only caught at two stations with *D. macrophthalmus* and *D. angolensis* as the only seabreams. The averages catch rates of the three shrimp species *P. longirostris*, *A. varidens* and *Nematocarcinus africana* were respectively 3.8, 13.4 and 72 kg/hour.

Biomass estimates

Biomass estimates in tonnes of the most important groups are presented in Table 5.2. The biomasses were calculated by stratifying by depth (200-299, 300-399, 400-499, 500-599, 600-699 and 700-799m). The CVs are weighted by stratum size.

The various strata have been sampled with different intensity throughout the time series and Annex VIII shows the numbers of trawls that have been done by strata and survey. The biomass estimates of the pelagic species may not reflect the true biomass, as pelagic species are often distributed too high in the water column to be available for the bottom trawl. Some of the biomass estimates in Table 5.2 have a high coefficient of variations (CV), which indicates that the trends in the time series should be interpreted with care.

The 2008 biomass estimate of hake was 6 000 tonnes, that is 1 000 tonnes lower than the 2007 biomass estimate of 7 000 tonnes, which was almost identical to the 2006 estimate. In 2004, the estimate of *M. polli* was 16 100 tonnes, but decreased with 37% from 2004 to 2005, and further with 30% from 2005 to 2006. The reasons of these reductions in biomass are not clear, but the large decline is of concern.

Seabreams were only found in a few stations in the shallow area of the slope (<280m). Thus care should be taken when comparing the biomass estimates of seabreams on the central slope. The 2008 estimate was 2 000 tonnes, 150% higher than the 2007 estimate of only about 800 tonnes. Both estimates were lower than the 2004 and 2005 estimates of 10 800 and 6 500 tonnes, respectively. As in previous surveys, the *D. macrophthalmus* was the most abundant seabream species on the central slope.

P. longirostris is distributed in depths between 200 and 400 m, and the biomass has increased from 340 tonnes in 2002 to about 1 300 tonnes in 2006 on the central slope. In 2008, the biomass estimate was 400 tonnes, which is higher than the 2007 biomass estimate of 191 tonnes and indicates a substantial increase in the abundance. However, the high CV shows that the estimates are imprecise.

The 2008 biomass estimate of *A. varidens* was 880 tonnes, which is considerably larger than the 2007 estimate of 650 tonnes. The trends of the biomass estimates show a consecutive increase during the 3 last years, that may indicate a certain recovering of this resource after the high estimate of 790 tonnes in 2005.

In contrast to the two previous shrimp species, the *N. africana* is not commercially important. Nevertheless, the 2008 biomass estimate of 5 000 tonnes was lower than the 2007 estimate of 7 900 tonnes, the highest ever recorded. The survey time series shows that the 2008 estimate is lower than the 2004, 2005 and 2006 estimates of 6 200, 5 600 and 5 300 tonnes respectively.

The biomass estimate of Ommastrephidae on the central slope in 2008 was 140 tonnes. This was the same as estimated in 2007, but considerably smaller than the 2005 and 2006 estimates of 510 and 460 tonnes, respectively. The biomass increased from 2001 to 2006, but the huge decrease in 2007 and 2008 suggests that the present abundance is still relatively low.

Hairtails were mainly caught in the shallower areas of the slope. The 2008 biomass estimate was 760 tonnes, more than three times the 2007 estimate of 185 tonnes. Both biomass were lower than estimates from the 2004, 2005 and 2006.

The biomass estimate of the sharks dropped to 390 tonnes in 2008 after the increase of 1000 tonnes in 2007, which was a large increase from previous surveys. However, the high CV and large variability in biomass between surveys show that there is no clear trend in the abundance of sharks.

Table 5.2 Biomass estimates (tonnes) of important species on the slope (200-800 m) in the central region. CV values are indicated in brackets.

Distribution

Figure 5.2 shows the distribution of hake (*M. polli*) in the central region. The distribution covers the whole central slope and is similar to the observations of last year survey. The highest densities were found off Pta. do Morro and Cabeça de Baleia at depths between 300 and 500 m.

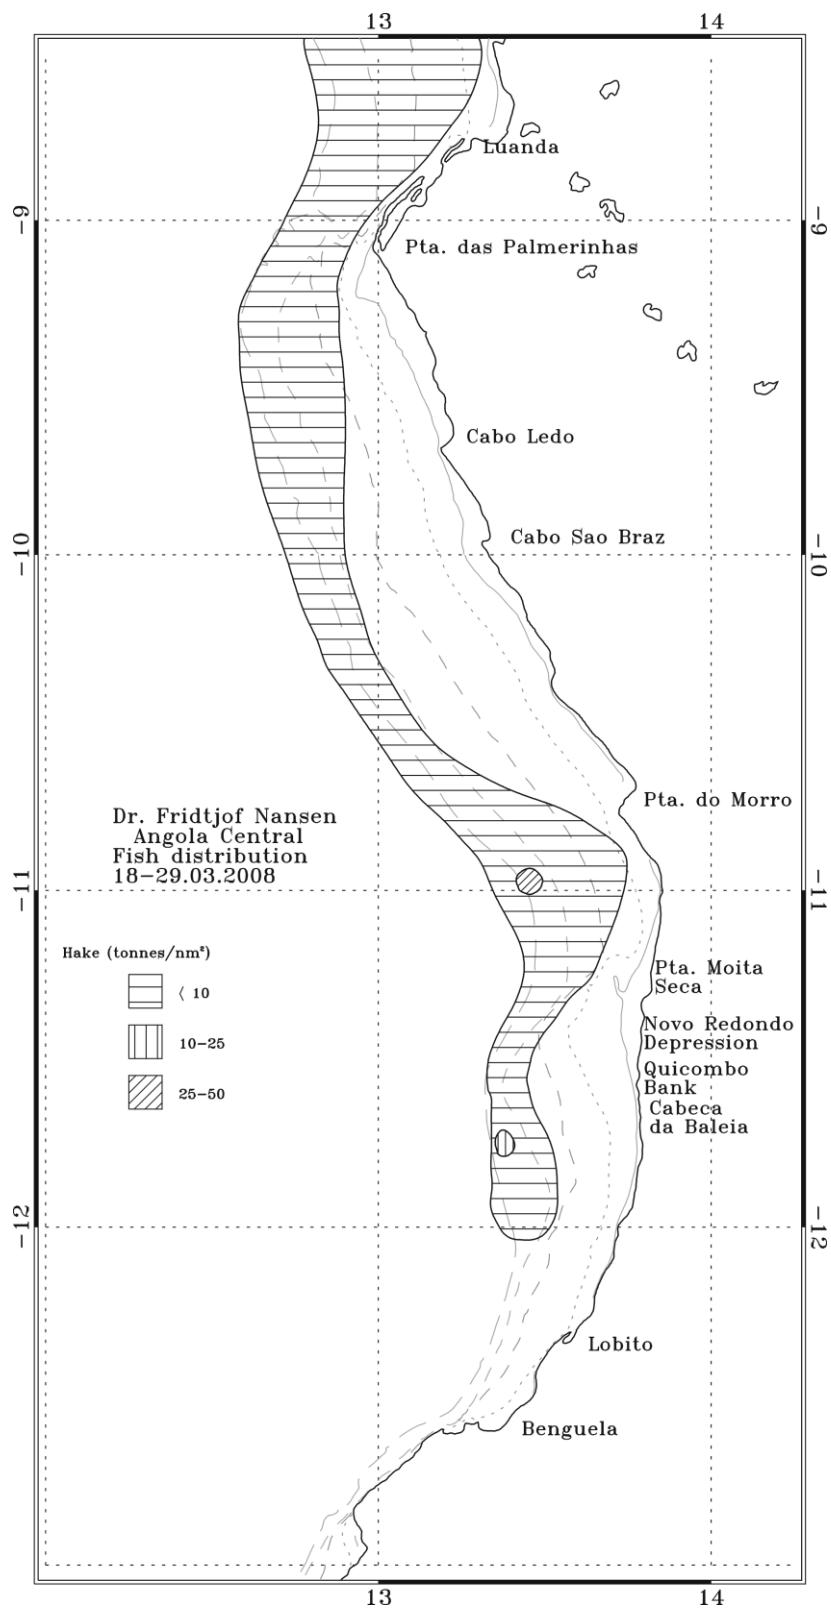

Figure 5.2 Distribution of Benguela hake (*Merluccius polli*) in the central region, Benguela-Luanda. Depth contours at 20, 50, 100, 200 and 500 m.

5.3 Luanda – Congo River slope

The survey covered the northern region of Angolan waters from Luanda to Congo River, and a total of 36 successful swept-area trawl stations were accomplished on the northern slope (Table 2.1). The area north of Congo River is at present inaccessible to fisheries surveys due to the restricted oil exploitation areas. In previous years, this area was covered by some of the surveys. However, only stations south of the Congo River were included in the time series of biomass presented in Table 5.3. The various strata have been sampled with variable intensity throughout the time series, and Annex VIII shows the numbers of trawls by strata by survey.

The average catch per hour of all species was 673 kg/hour (Annex VI), and the ‘demersal’ group contributed 13% to the mean catch rate, the ‘pelagic’ group 2%, and the shrimps, cephalopods and sharks each contributed 24, 1 and about 1%, respectively. The “other” group dominated the catches and contributed 58% to the total mean catch rate. *M. polli* was caught in 83% of the stations, and the average catch rate was 53 kg/hour. Seabreams were only caught in six stations on the northern slope, and the average catch rate (which consisted almost entirely of *D. angolensis*) was 5.6 kg/hour. The averages catch rates of the three shrimp species *P. longirostris*, *A. varidens* and *N. africana* were respectively 8, 6 and 148 kg/hour.

Biomass estimates

Biomass estimates in tonnes of the most important species groups are presented in Table 5.3. The biomasses were calculated by stratifying by depth (200-299, 300-399, 400-499, 500-599, 600-699 and 700-799m).

Pelagic species are often not available for the bottom trawl as the fish swim too high above the seabed and the biomass estimates of the pelagic species may reflect their availability to the trawl and not only their abundance. Some of the biomass estimates in Table 8.3 have a high coefficient of variation (CV), which indicates that the trends in the time series should be interpreted with care.

Figure 8.3 shows the estimated distribution area of hake (*M. polli*) in the northern region. The stock distribution covers the slope from Luanda to Congo River with densities <10 tons/NM².

The biomass estimate of seabreams in 2008 was about 629 tonnes, which is similar to the 2007 estimate of 612 tonnes. The slope is not within the main distribution of seabreams, and there is no clear trend in the time series of this biomass estimates. As in previous surveys, the *D. angolensis* was the most abundant seabream on the northern slope.

The biomass estimates of *M. polli* increased to 5 925 tonnes after the decrease registered from 2004 to 2007, with 15 300, 11 000, 7 553 and 4 117 tonnes respectively.

P. longirostris is distributed in depths between 200 and 400 m, and the biomass shows a small decrease from 981 tonnes in 2007 to about 933 tonnes in 2008 on the northern slope. However, the high CVs indicate that the estimates are not very precise.

The 2008 biomass estimate of *A. varidens* was 615 tonnes, which is 65% higher than the 2007 estimate of 373 tonnes, and considerably higher than the 2002 estimate of 127 tonnes. There are no clear trend after the low estimate in 2002.

The *N. africana* is not a commercially important species, however, the 2008 biomass of about 15 267 tonnes is the highest estimate in the time series. Compared to the estimates of 2000-2003, the most recent surveys indicate a high and stable abundance of *N. Africana*.

The biomass estimate of Ommastrephidae in 2008 was 205 tonnes, which is 64% higher than the 2007 estimate of 125 tonnes, the lowest estimate since 1996.

The 2008 biomass estimate of hairtails was 1 365 tonnes, which is 82% higher than the 2007 estimate of 749 tonnes, the lowest of the time series from 1992 to 2008. The high CVs and the annual variability in the biomass estimates make it difficult to conclude on the trend in biomass in recent years.

The biomass estimate of the sharks in 2008 was 846 tonnes, which still is a decrease from the 2005 estimate of 1 180 tonnes. However, there is no clear long time trend in the abundance of sharks.

Distribution

Figure 5.3 shows the estimated distribution of hake (*M. pollii*) in the northern region. The stock distribution covers the slope from Luanda to the Congo River with densities <10 NM² in all the northern extension of distribution.

Table 5.3 Biomass estimates (tonnes) of important species on the slope (200-800 m) in the northern region. CV values are indicated in brackets.

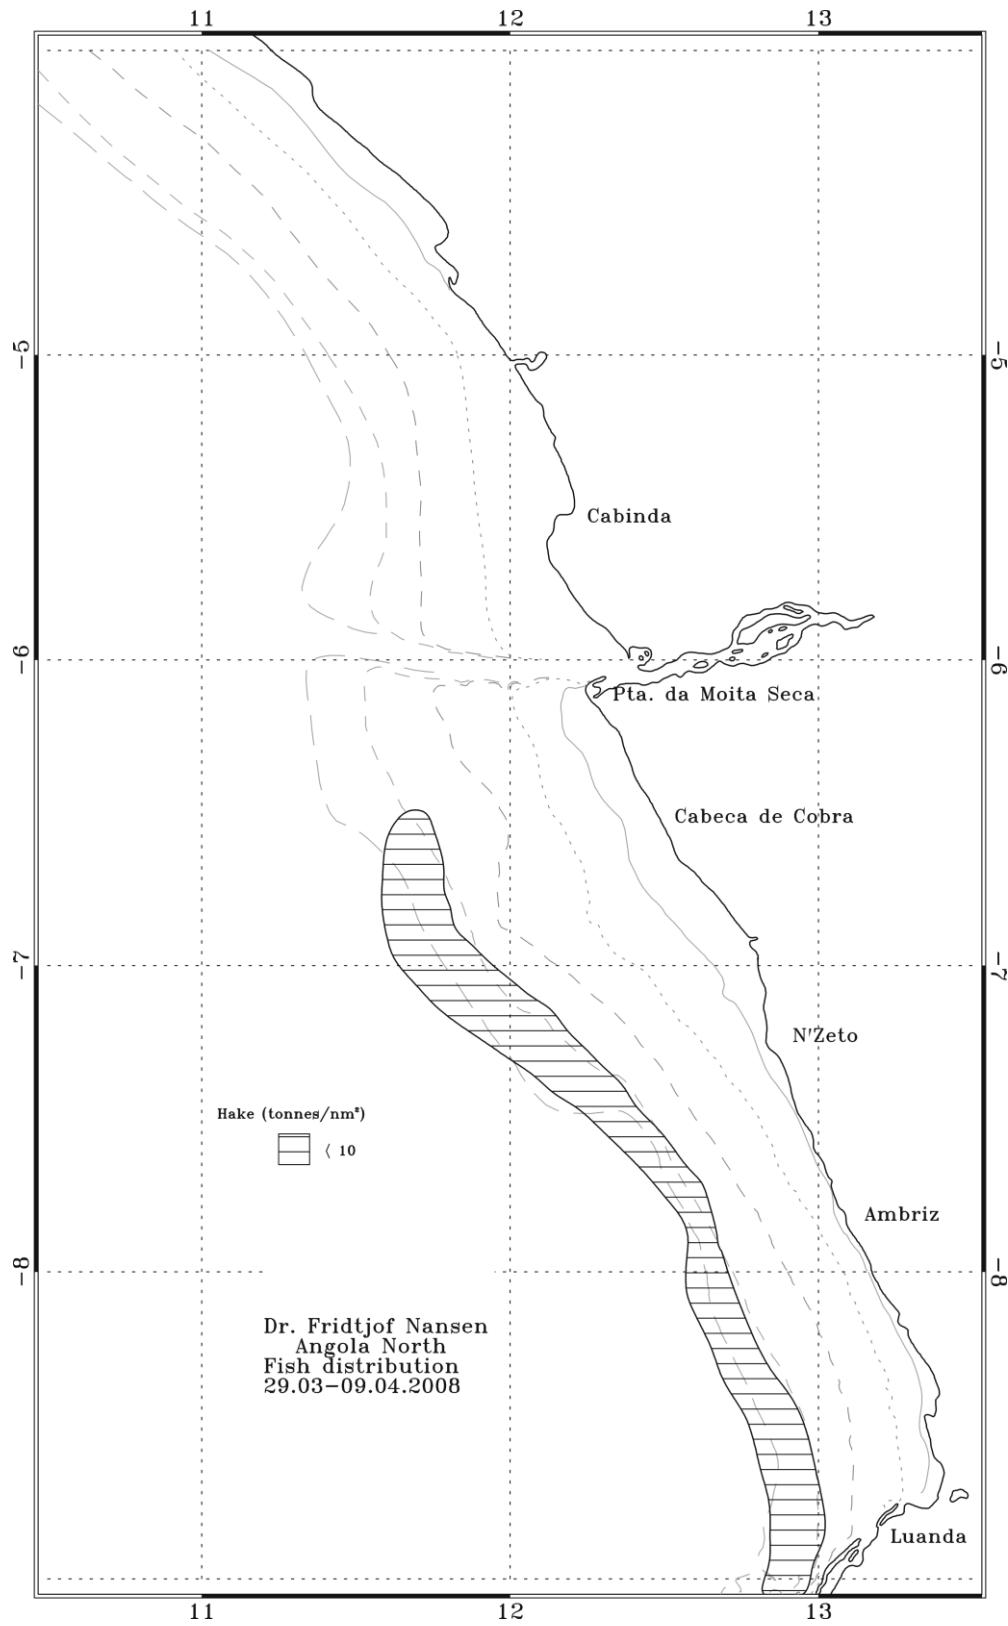

Figure 5.3 Distribution of hake (*Merluccius polli*) in the northern region, Luanda – Congo River. Depth contours at 20, 50, 100, 200 and 500 m.

CHAPTER 6 SUMMARY

From 10 March to 13 April the 2008 demersal resource survey off Angola was successfully carried out using R/V “Dr. Fridtjof Nansen”. Except from the area between Tombua and Benguela, which is unsuitable for trawling due to poor bottom conditions, the shelf and upper slope (20-800 m) from Cunene River to Congo River was covered.

In total, 199 trawl stations were conducted of which 193 were valid and used in biomass estimation of the demersal stocks. To map the oceanographic conditions 310 CTD samples were carried out.

6.1 Hydrographic conditions

The demersal surveys in March are coincident with the late phase of the wet season, which causes low salinity in the surface waters on the shelf off northern and central Angola due to the freshwater coming for the coastal rivers. Signal of up welling was observed in the southern region. In the central region, the temperature varied between 24–28°C, and the lowest temperature (24°C) was observed around Cabo Ledo. The salinity values ranged between 35.1 and 35.7, maybe related to an upwelling situation. In the northern region the temperature was lowest close to the river’s mouth (about 24°C), while offshore it was around 29 °C. Inshore waters presented low salinity values, particularly around the river’s mouth (29) and increasing at the same latitude to 33 further offshore. The influence of the river’s plume was observed down to 8.5°S with a salinity of 33.5, while further south there was no sign of freshwater.

6.2 Biomass estimates

Table 6.1 presents the time series from 1985 to 2008 of the biomass estimates of the most important species on the shelf and slope in the central and northern regions in Angola. The southern region is not included, as the surveys in this region have not been properly standardized throughout the years. However, the effort, *i.e.* the number of stations by stratum on the southern shelf, is relatively similar from 2000 to 2008 (Annex VIII) and the estimates in this period are comparable. The estimates on the southern slope are very unreliable as the number of tows is very low due to difficult trawling conditions. Table 4.1 and Table 5.1 show the biomass estimates of the important species on the southern shelf and slope, respectively.

Seabreams

The seabream biomass estimate in the southern region was about 9 150 tonnes and consisted almost entirely of *D. macrophthalmus*. This is a marked decrease from last year, and the lowest in the timeseries. In the central and northern regions, the biomass estimate of seabreams in 2008 was about 21 227 tonnes, which is a 14% reduction from 2007. *D. macrophthalmus* and *D. angolensis* comprised 15% and 32%, respectively, of the 2008 estimate. Other abundant seabreams are *P. bellottii*, *D. canariensis* and *D. barnardi*. The biomass estimates of seabreams have fluctuated since 2000, and there is no clear long-term trend in the time series.

Hakes

M. capensis is generally the dominating hake species in the south, and Angola shares this stock with Namibia. However, whilst no Benguela hake (*M. polli*) was caught on the southern shelf during the 2006 survey the species contributed to about 65% of the biomass in 2008. The total biomass estimate of hake (*M. capensis* and *M. polli*) on the southern shelf and slope in 2008 were 1 700 and 950 tonnes, respectively. Only one valid station was carried out on the slope between 200 and 600 meters which make the 2008 estimate for the slope unreliable. On the shelf the hake abundance has declined annually since 2003, and the 2008 estimate is the lowest observed since 2000. The decrease is a reason for concern. In the central and northern regions, *M. polli* is the only hake species. Here, the estimated biomass of hake (*M. polli*) was 11 979 tonnes, which is a 7% increase from the 2007 estimate. Furthermore, the 2008 estimate is about 62% lower than the 2004 estimate.

Shrimps

The two commercially important shrimp species *P. longirostris* and *A. varidens* are never found in high densities south of Tombua, and they were not caught in 2006 or 2007. However, in 2008 both *P. longirostris* and *A. varidens* were caught in small quantities in the southern region. In 2008, the biomass estimate of *P. longirostris* for the central and northern regions was 1 622 tonnes, which is a 21% increase from the 2007 estimate. The high CV indicates that the estimate is relatively uncertain,. The 2008 estimate of *A. varidens* was 1 508 tonnes, which is a 47% increase from 2007.

Grunts

Commercially important grunt species are *P. incisus* and *P. rogeri*, but no grunts were caught in the southern region. The biomass estimate of grunts in the central and northern regions in 2008 was 7 411 tonnes, which is a 57% reduction from 2007 (17 242 tonnes), which is the highest biomass estimate registered since 1985.

Croakers

South of Tombua, the biomasses of the croakers have varied considerably between surveys during the last years, therefore, no clear trend in the time series can be seen. However, the 2008 estimate of 400 tonnes is a large decrease from last year's estimate of 4 200 tonnes and it is the lowest in the timeseries. The estimates of *Umbrina canariensis*, which is one of the most important croakers, also show large annual variation and there is no evident trend in the time series. The biomass estimate of croakers, mainly *U. canariensis*, *A. aequidens*, *P. senegalensis* and *P. typus*, in the central and northern regions was about 12 684 tonnes in 2008, which is a 6% increase from 2007.

Groupers and snappers

Groupers and snappers are not distributed in the region south of Tombua. In the central and northern regions the biomass estimates for these groups are relatively imprecise as shown by the high CVs values. The 2008 biomass estimate of groupers increased from 950 in 2007 to 1 187 tonnes, while the biomass estimate of snappers dropped to 90 tonnes from 113 tonnes in 2007. The estimates in the time series show large fluctuations, making it difficult to identify any trend and conclude on the current state of these stocks.

Pelagic species

For the pelagic species, the estimates of the biomass are characterized by the high variability throughout the years, particularly for horse mackerel, hairtail and barracuda. The bottom trawl is not an adequate sampling gear for the pelagic fish species; therefore no certain conclusion

may be drawn for these resources. More adequate results are achieved from the acoustic surveys conducted in July and August.

Table 6.1 Biomass estimates (tonnes) of important species in the central and northern regions. CVs are in brackets.

ANNEX IV Equations

1. Biomass estimates

The stratified estimator of mean density in the entire area is calculated as (Cochran, 1977)

$$\bar{y}_{st} = \sum_{i=1}^L W_i \bar{y}_i, \quad (1)$$

where

L is the number of strata,

$W_i = \frac{\text{area}_i}{\text{total area}}$ is the proportion of the i^{th} stratum of the total survey area,

$\bar{y}_i = \frac{\sum_{k=1}^{n_i} y_{i,k}}{n_i}$ is the average density in the i^{th} stratum

$y_{i,k}$ is the density [tonnes/NM²] by the k^{th} tow in stratum i

n_i is the number of tows in the i^{th} stratum.

The total biomass in the area is calculated by

$$B = \bar{y}_{st} \cdot \text{total area} \quad (2)$$

The estimated variance of the biomass ($\text{var}(\text{biomass})$) was calculated by:

$$\text{var}(\text{biomass}) = \left(\sum_{i=1}^{n_i} \frac{W_i^2 s_i^2}{n_i} \right) A^2 \quad (3)$$

where

$$s_i^2 = \frac{\sum_{k=1}^{n_i} (y_{i,k} - \bar{y}_i)^2}{n_i - 1}, \text{ and } A \text{ is total area}$$

The standard error (SE) of the stratified mean was calculated as (Cochran 1977):

$$SE = \sqrt{\text{var}(\text{biomass})} \quad (4)$$

The precision for the estimates (CV) was calculated by (Zar 1999¹):

$$CV = \frac{SE}{biomass} \quad (5)$$

If the sample size is “large” enough, then the Central Limit Theorem states that each time a survey is conducted there is a 95% chance that the true mean is in the interval (see Cochran², 1977)

$$biomass \pm t_{\alpha/2} SE \quad (6)$$

where t is from Students t-table with $(n-1)$ degrees of freedom and $\alpha = 0.025$.

ANNEX VI. Catch rates

Families included under each group:

Demersal: Sciaenidae, Sparidae, Pomadasytidae, Ariidae, Serranidae, Lutjanidae, Merlucciidae, Ophidiidae, Lethrinidae.

Pelagic: Scombridae, Sphyridae, Trichiuridae, Clupeidae, Engraulidae, Carangidae.

Cephalopods: squids and octopuses.

Catch rates (kg/hour) by main demersal caught in valid swept area bottom trawl hauls on the shelf. Southern region.

A: Inner shelf (20-70 m), B: Outer shelf (71-200 m).

A. Inner shelf (20-70 m).

ANNEX VII Instruments and fishing gear used

The Simrad ER-60/18, 38, 120 and 200kHz scientific sounder was run during the survey only for observation of fish and bottom conditions.

Standard sphere calibrations were carried out using 38.1 mm diameter tungsten carbide sphere for 18, 38, 120 and 200 kHz. The calibrations took place 18.03.2008, Baia dos Elefantes. The details of the settings of the 38kHz echo sounder where as follows:

Transceiver-2 menu (38 kHz)

Transducer depth	5.50 m
Absorbtion coeff.	8,7 dB/km
Pulse length	medium (1,024ms)
Bandwidth	2,43 kHz
Max power	2000 Watt
2-way beam angle	-20,6dB
gain	25,04 dB
SA correction	-0,46 dB
Angle sensitivity	21.9
3 dB beamwidth	7,76° along ship 7,86° athwardship
Alongship offset	-0.12°
Athwardship offset	0.06°

Bottom detection menu Minimum level -40 dB

Fishing gear

The vessel has two different sized "Åkrahann" pelagic trawls and one "Gisund super bottom trawl". During the present survey only the bottom trawl was used.

The bottom trawl has a headline of 31 m, footrope 47 m and 20 mm meshsize in the codend with an innernet of 10 mm meshsize. The trawl height was about 4.5 m and distance between wings during towing about 21 m. The sweeps are 40 m long. The trawl is equipped with a 12" rubber bobbins gear. New doors are 'Thyborøn' combi type, 7.41 m², 1720 kg. These have been in used onboard since 19.02.08. During the present survey the door distance was kept nearly constant at about 50 m at all depths by the use of a 9.5 m strap between the wires at 120 m distance from the doors (normally applied at depths greater than 80 m). At depths greater than 300 m the trawl was equipped with a tickler chain, which improves the catchability of bottom living and borrowing species, particularly shrimps.

The SCANMAR system was used on all trawl hauls. This equipment consists of sensors, a hydrophone, a receiver, a display unit and a battery charger. Communication between sensors and ship is based on acoustic transmission. The doors are fitted with sensors to provide information on their distance, and the trawl was equipped with a trawl eye that provides information about the trawl opening. A catch sensor on the cod-end indicated the size of the catch.

ANNEX VIII Station allocation by survey and depth strata

Numbers of valid bottom trawl stations by depth strata. Angolan demersal surveys 1985-2008.
